Edited by Laurie H. Glinscher, Harvard School of Public Health, Boston, MA, and approved February 10, 2005 (received for review December 3, 2004)

We analyzed the serum and cerebrospinal fluid (CSF) leptin secretion and the interaction between serum leptin and CD4⁺CD25⁺ regulatory T cells (TRegs) in naive-to-therapy relapsing-remitting multiple sclerosis (RRMS) patients. Leptin production was significantly increased in both serum and CSF of RRMS patients and correlated with IFN-γ secretion in the CSF. T cell lines against human myelin basic protein (hMBP) produced immunoreactive leptin and up-regulated the expression of the leptin receptor (ObR) after activation with hMBP. Treatment with either anti-leptin or anti-leptin-receptor neutralizing antibodies inhibited secretion in vitro but can expand in vivo (9). Although the mechanisms operated by TRegs in suppression are not fully delineated, the forkhead transcription factor FoxP-3 seems to be required for suppression to occur (9).

Here, we report increased leptin levels in CSF and serum of naive-to-therapy RRMS patients and an inverse correlation with TRegs frequency. These findings may be relevant in better understanding the disease pathogenesis and may have therapeutic implications.

Materials and Methods

Subjects. All MS patients and controls were recruited at the Università di Napoli “Federico II.” For serum and CSF leptin measurement, we included in the study 126 individuals (Table 1) with MS defined according to the criteria of McDonald et al. (16) and 117 age-, gender-, and body mass index (BMI)-matched controls with other noninflammatory neurologic disorders (NIND). All MS patients had RRMS and an expanded disability status scale score of ≤3.5 and were naïve to treatment. The inclusion criteria for RRMS patients were (i) onset of relapse within 4 weeks of serum/CSF collection, (ii) a history of at least two clinical relapses during the preceding 2 years, and (iii) the presence of one or more enhancing lesions on MRI at the time of entry into the study. NIND included Parkinson’s disease, spinocerebellar degeneration, amyotrophic lateral sclerosis, brain tumors, cranial trauma, nonspecific headache, and hydrocephalus. We additionally included, for only serum leptin measurement and the immune-phenotypic analysis, 27 donors who were healthy age-, sex-, and BMI-matched with the RRMS and NIND populations. None of the NIND and healthy controls had a history of autoimmune disorders, infection, or endocrine disease. The study was approved by the institutional ethics committee and all individuals gave written informed consent.

Leptin and IFN-γ Measurement. All serum and CSF samples were collected at 8:30 a.m. after overnight fast and stored at −80°C. For leptin measurement, a human leptin ELISA kit (R&D Systems) was used according to the manufacturer’s instructions. Human IFN-γ and IL-4 were measured in the CSF, in parallel with leptin, with ELISA kits (Endogen, Cambridge, MA).

This paper was submitted directly (Track II) to the PNAS office.

Abbreviations: BMI, body mass index; CSF, cerebrospinal fluid; EAE, experimental autoimmune encephalomyelitis; EAE; RRMS, relapsing–remitting MS; Th-1, T helper 1; TRegs, regulatory T cells.

It has recently been shown that leptin, a cytokine-like hormone mainly secreted by adipocytes, can play a significant role in the pathogenesis of several autoimmune diseases, such as experimental autoimmune encephalomyelitis (EAE), antigen-induced arthritis, and experimentally induced colitis (1–6). EAE is an animal model for the human demyelinating disease multiple sclerosis (MS) (7, 8). EAE can be induced in susceptible strains of mice through immunization with myelin antigens or by adoptive transfer of myelin-specific T helper 1 (Th-1) cells (7, 8). Genetically leptin-deficient (ob/ob) mice are resistant to the induction and progression of EAE, and WT EAE-susceptible mice show an increase in serum leptin preceding the clinical onset of the disease that correlates with inflammatory anorexia and disease susceptibility (2, 3). In addition, pathogenic Th-1 cells and macrophages in active EAE brain lesions secrete consistent amounts of leptin (3). These data account for an involvement of leptin in CNS autoimmunity, at least in the EAE model. Despite this finding, in humans, the role of leptin in the pathogenesis of MS is not yet fully elucidated. In this study, we analyzed the secretion of leptin in the cerebrospinal fluid (CSF) and serum of naïve-to-treatment relapsing–remitting MS (RRMS) patients and leptin’s interaction with the CD4⁺CD25⁺ regulatory T cells (TRegs). TRegs are known to dampen autoreactive responses mediated by CD4⁺CD25⁺ T cells and may influence the onset and progression of autoimmunity (9). In mice, depletion of TRegs is associated with autoimmunity, and defects of TRegs have been described in nonobese diabetic mice and in humans with type 1 diabetes (9, 10). Also, reduced frequency of TRegs and/or defective suppressor function have been observed in humans with systemic lupus erythematosus, juvenile idiopathic arthritis, autoimmune polyglandular syndrome type II, and RRMS (11–15). TRegs are anergic in vitro but can expand in vivo (9). Although the mechanisms operated by TRegs in suppression are not fully delineated, the forkhead transcription factor FoxP-3 seems to be required for suppression to occur (9).

Here, we report increased leptin levels in CSF and serum of naïve-to-therapy RRMS patients and an inverse correlation with TRegs frequency. These findings may be relevant in better understanding the disease pathogenesis and may have therapeutic implications.
Flow Cytometry. Immunophenotypic analysis of peripheral blood from RRMS patients and healthy controls was performed with an EPICS XL flow cytometer (Beckman Coulter) using the Beckman Coulter software program XL system II. Triple combinations of various anti-human mAbs were used (Coulter Immunotech, Marseille, France). All samples were analyzed within 3–4 h of sampling, and staining was performed according to standard procedures as described in ref. 17.

CD4+CD25+ T<sub>Reg</sub> in various mouse strains were analyzed by flow cytometry with a FACSCalibur flow cytometer (Becton Dickinson) and the Becton Dickinson software program CELLQUEST. mAbs were added to single cell suspensions of lymphocytes from spleens and lymph nodes after lysis with the ACK buffer [0.15 M NH₄Cl/10 mM KHCO₃/0.1 mM Na₂EDTA (pH 7.4)]. The analysis and quantification of the T<sub>Reg</sub> population was obtained by gating on CD4+ T cells.

Human Myelin Basic Protein (hMBP) T Cell Lines. hMBP-specific short-term T cells lines were generated according to a method reported in ref. 18. The T cell lines were derived from peripheral blood lymphocytes of three naïve-to-treatment RRMS patients.

Proliferation and Suppression Assays. For in vitro blocking experiments, Abs against human lefntin provided by Radek Sokol (Bio-Vendor, Brno, Czech Republic) and mAb against the human lefntin receptor (R & D Systems) were used at a final concentration of 10–25 µg/ml; the control was irrelevant IgG Ab (BioVendor).

The in vitro suppressive capacity of T<sub>Reg</sub> isolated from RRMS patients and healthy controls was measured after magnetic cell sorting by using the Dynal CD4+CD25+ T<sub>Reg</sub> kit (Dynal, Oslo). Briefly, CD4+CD25+ T cells (5 × 10⁶ cells per well) were cocultured with CD4+CD25+ (5 × 10⁶ cells per well) in a 1:1 ratio (both 98% pure) and stimulated with 5 µl of anti-CD3/CD28 Dynabeads (0.1 bead per cell) (Dynal). In mice, T<sub>Reg</sub> were isolated with the Regulatory T Cell Isolation kit (Miltenyi Biotec, Gladbach, Germany) and stimulated with anti-CD3 antibody (2C11 hybridoma) at 200 ng/ml final concentration and irradiated (30 Gy) T cell-depleted syngeneic splenocytes (1:1 ratio, 5 × 10⁶ cells per well).

Immunocytochemistry. T cells cultured, or not, with hMBP were washed twice with PBS on d 5 of culture, spotted onto glass slides, and fixed with methanol for 2 min. Leptin and ObR were detected with polyclonal Abs (Santa Cruz Biotechnology) (3).

Mice. Female ob/ob (C57BL6/J-ob/ob), WT controls (C57BL6/J-WT), female lefntin-receptor-deficient (db/db) mice (C57BL-Ks-db/db), C57BL-Ks-db/+ controls (db/+), and SJL/J mice (all 6–8 weeks old) were obtained from Harlan Italy (Corezzana, Italy). Experiments were performed following the guidelines of the Istituto Superiore di Sanità, Rome.

*The CSF leptin index is a measure of in situ synthesis of leptin in the CNS, calculated with the following formula: (CSF leptin/CSF albumin)/(serum leptin/serum albumin).

EAE Induction and Treatment with the Fusion Protein of ObR and the Fc Fragment of IgG (ObR:Fc). The peptide used for EAE induction in SJL/J female mice was the proteolipid protein peptide (PLP)139–151 (HSLGKWLGHPDKF). The peptide was synthesized by INBIOS (Pozzuoli, Italy), purity was assessed by HPLC (>97% pure), and amino acid composition was verified by mass spectrometry. For EAE induction, mice were immunized s.c. in the flank with 100 µl of complete Freund’s adjuvant (Difco) emulsified with 100 µg of PLP139–151 peptide on d 0 and with 200 ng of pertussis toxin (Sigma) i.p. on d 0 and d 1. Mice were scored for clinical symptoms and weighed daily according to a system described in refs. 2 and 3. Brains and spinal cords were dissected 15–20 d after immunization and fixed in 10% formalin. Paraffin-embedded sections of 5 µm thickness were stained with hematoxylin/eosin, and sections from 4–10 segments per mouse were examined blindly for the number of inflammatory foci by using a scoring system described in ref. 3.

The chimeric fusion protein ObR:Fc (R & D Systems) in 200 µl of PBS was injected i.p. at a dose of 100 µg per mouse per day for three consecutive days. Thus, treatment with ObR:Fc of SJL/J mice was performed on d −1, d 0, and d +1 both before and after PLP139–151 immunization. The same amount of control IgG was injected i.p. in the control SJL/J mice.

Real-Time Quantitative PCR. mRNA was extracted from purified CD4+CD25+ cells (98% pure by FACS analysis) by using the MicroFastTrack 2.0 kit followed by cDNA synthesis with the SuperScript System (Invitrogen). Expression levels of the transcription factor FoxP3 were analyzed by real-time quantitative PCR (TaqMan gene expression assay) by using an ABI PRISM 7700 thermal cycler (Applied Biosystems). TaqMan primers and probes for FoxP3 and for the housekeeping gene GAPDH were purchased as premade kits (Applied Biosystems). For relative quantitation of gene expression to the endogenous control, the comparative C<sub>T</sub> method was used in accordance with the manufacturer’s guidelines. Results are expressed as the percentage of FoxP3 increase compared with CD4+CD25− effector T cells.

Statistical Analysis. Nonparametric analyses were performed by using the Mann–Whitney U test for unrelated two-group analyses. The ANOVA test was used to assess differences between groups.
Increased Serum and CSF Leptin in Naïve-to-Treatment RRMS Patients Correlates with IFN-γ Production in CSF.

We found that leptin was increased in both serum and CSF of naïve-to-therapy RRMS patients (Table 1 and Fig. 1 a–d). These differences were maintained even when serum and CSF leptin were normalized for BMI (Table 1 and Fig. 1 a–d). In addition, as expected, serum and CSF leptin secretion positively correlated with BMI in NIND controls (Fig. 1 b and d). This correlation was lost in RRMS patients (Fig. 1 a c). Conversely, the correlation between serum leptin and CSF leptin was maintained in both RRMS patients and NIND controls; however, this correlation was stronger in NIND controls than in RRMS patients (Fig. 1 e and f). We also compared the CSF-leptin/serum-leptin ratio and observed a statistically significant increase of this value in RRMS (Table 1). This evidence was further supported by the lack of increase of albumin in the CSF of RRMS patients, a marker of blood–brain-barrier (BBB) damage. In addition, we calculated the CSF-leptin/CSF-albumin ratio as a further indicator of BBB integrity and the CSF leptin index, calculated as the (CSF leptin/CSF albumin)/(serum leptin/serum albumin), to evaluate the in situ production of leptin by CNS. As shown in Table 1, the CSF-leptin/CSF-albumin ratio and the CSF leptin index were higher in RRMS patients (Table 1), suggesting the production of leptin by CNS in RRMS.

Finally, we measured the amount of IFN-γ and IL-4 in CSF and observed a significant increase in IFN-γ (Table 1) and a positive correlation with CSF leptin secretion in RRMS patients only (Fig. 1 g and h). IL-4 did not show any significant increase in CSF, and the concentration of IL-4 was always below the detection limit of the assay in both RRMS and NIND controls (data not shown).

Simple regression analysis and the Pearson’s correlation coefficients were adopted to study the relationship between different variables. The program used was Statview (Abacus Concepts, Cary, NC). Results are expressed as mean ± SD; P < 0.05 was considered statistically significant.

Results

Increased Serum and CSF Leptin in Naïve-to-Treatment RRMS Patients Correlates with IFN-γ Production in CSF.

Fig. 1. Naïve-to-therapy RRMS patients show an increased secretion of leptin in serum and CSF that correlates with IFN-γ production in CSF. Statistical analyses of these data are summarized in Table 1. (a and b) Simple regression analysis between serum leptin and BMI in RRMS patients (n = 126) and NIND controls (n = 117). The correlation was lost in RRMS patients, whereas correlation was maintained in NIND controls. (c and d) The correlation between CSF leptin and BMI was lost in RRMS patients whereas correlation was very strong in NIND controls. (e and f) Simple regression analysis between the CSF leptin and the IFN-γ levels in CSF in both RRMS patients and NIND controls; the correlation was stronger in patients than in controls. (g and h) Simple regression analysis between the CSF leptin and the IFN-γ levels in CSF. In NIND controls, the IFN-γ average levels were very low (see Table 1), and no correlation was observed with CSF leptin.

Fig. 2. T cell lines against hMBP derived from naïve-to-treatment RRMS patients produce immunoreactive leptin, up-regulate the ObR, and are inhibited in their proliferation by anti-leptin or anti-leptin-receptor blocking antibodies. (a–c) Expression of leptin in T cells from a naïve-to-treatment RRMS patient in the presence of medium alone (a) or after activation with hMBP (b and c). Leptin was detectable only after activation in the cytoplasm of T cells. (d–f) Expression of ObR on T cells in the presence of medium only (d) or after activation with hMBP (e and f). The ObR was expressed at very low levels before activation and was significantly up-regulated on the cell membrane after activation with hMBP (e and f). All photos show immunoperoxidase staining with diaminobenzidine chromogen (brown) and hematoxylin counterstaining (violet). The open squares in a and b represent the zone of higher magnification shown in c and f, respectively. (Magnification: a, b, d, e, and f, ×100; c and f, ×400.) (g) Anti-hMBP short-term T cell lines secrete immunoreactive leptin. (h) The anti-hMBP proliferative response of T cells is inhibited by the addition to cell cultures of either of the anti-Ob or anti-ObR antibodies. The data shown are from one representative experiment of three.
RRMS Patient-Derived T Cell Lines Activated with hMBP Produce Immunoreactive Leptin and Up-Regulate the ObR. To investigate whether leptin could be secreted by hMBP-activated autoreactive T cells present in the CNS, we generated short-term T cell lines from RRMS patients and stained them with leptin- and ObR-specific antibodies. As shown in Fig. 2 a–f, hMBP-activated T cells from three naïve-to-therapy RRMS patients produced consistent amounts of leptin and up-regulated the ObR. The production of leptin was also confirmed with the measurement of immunoreactive leptin in the culture medium by a human-leptin-specific ELISA (Fig. 2g).

Neutralization of Leptin or Its Receptor Inhibits T Cell Activation of hMBP-Specific T Cell Lines Derived from RRMS Patients. We measured the proliferative response against hMBP on T cells from three naïve-to-treatment RRMS patients and added either an anti-leptin or an anti-leptin-receptor blocking antibody to the culture medium (Fig. 2h). We observed a significant reduction in the proliferative response of all three patients tested, ranging from 45% to 60% inhibition of proliferation (Fig. 2h).

Inverse Correlation Between Serum Leptin and Circulating TRegs in Naïve-to-Treatment RRMS Patients. The analysis of the immune phenotype was also performed on the peripheral blood of 31 individuals from the naïve-to-therapy RRMS patient population, selected on the basis of increase in serum leptin concentration (a serum leptin increase to ≥2.5-fold higher than the mean serum leptin observed in NIND and healthy controls). We compared these phenotypes with the immune phenotype of 27 healthy controls matched for age, sex, and BMI. The relative percentage and the absolute cell count per mm³ of the CD3⁺, CD4⁺, CD8⁺, CD19⁺, CD3⁻CD16⁻CD56⁻, and CD4⁺CD25⁺ TRegs subpopulations were performed (see Table 3, which is published as supporting information on the PNAS web site). Interestingly, naïve-to-therapy RRMS patients, selected on the basis of their serum leptin increase, showed a significant reduction in the percentage and absolute number of TRegs in the peripheral blood (Fig. 3a and Table 3), whereas no difference was observed in the frequency of the other cell subpopulations (Table 3). TRegs measurement in healthy controls was in agreement with that found in other studies (14). Regression analysis between serum leptin and the percentage of TRegs showed an inverse correlation in RRMS patients (Fig. 3b) but not in the controls (Fig. 3c). In vitro analysis of TRegs-mediated suppression in RRMS patients indicated a reduced ability to suppress T cell proliferation as compared with healthy controls (Fig. 3d), as reported in ref. 15. Moreover, the addition of leptin (100 ng/ml) to human TRegs alone, or during coculture with CD4⁺CD25⁺ effector cells, did not alter significantly either proliferation or the suppressive capacity of TRegs (see Fig. 5a and b, which is published as supporting information on the PNAS web site).

ob/ob and db/db Mice Have Increased TRegs. To analyze in more detail the effect of leptin on the generation of TRegs in the periphery, we measured the effect of chronic leptin deficiency on the number of TRegs in ob/ob mice. These mice showed an increased frequency of TRegs in lymphoid organs when compared with normal WT mice (10.4 ± 3.7% vs. 4.7 ± 1.7%, respectively; P < 0.02). In addition, we counted TRegs in the lymphoid organs of db/db mice and, again, observed an increased percentage of TRegs when compared with db/+ heterozygote controls (13.9 ± 1.9 vs. 7.9 ± 0.9, respectively; P < 0.01). Finally, the suppressive capacity and phenotype of TRegs from db/db mice were evaluated. No significant differences were observed in terms of either suppressive capacity or hyporesponsiveness of TRegs (see Fig. 6 a–c, which is published as supporting information on the PNAS web site). In addition, expression levels of FoxP3 in TRegs of ob/ob and db/db mice were comparable to those in normal control mice (Fig. 6d).

ObR:Fc Soluble Chimera Increases the Number of TRegs and Ameliorates Clinical Course and Progression of Relapsing EAE (R-EAE). Treatment of normal R-EAE-susceptible SJL/J mice with anti-leptin

![Graph](image)

**Fig. 3.** Inverse correlation between serum leptin and circulating TRegs in RRMS patients. (a) The immune phenotype of circulating lymphocytes in RRMS patients selected on the basis of their increase in serum leptin (RRMS patients with a serum leptin increase to ≥2.5-fold higher than the mean serum leptin observed in NIND and healthy controls) revealed a significant reduction in the percentage and absolute number of TRegs in the peripheral blood (Fig. 3a and Table 3), whereas no difference was observed in the frequency of the other cell subpopulations (Table 3). TRegs measurement in healthy controls was in agreement with that found in other studies (14). Regression analysis between serum leptin and the percentage of TRegs showed an inverse correlation in RRMS patients (Fig. 3b) but not in the controls (Fig. 3c). In vitro analysis of TRegs-mediated suppression in RRMS patients indicated a reduced ability to suppress T cell proliferation as compared with healthy controls (Fig. 3d), as reported in ref. 15. Moreover, the addition of leptin (100 ng/ml) to human TRegs alone, or during coculture with CD4⁺CD25⁺ effector cells, did not alter significantly either proliferation or the suppressive capacity of TRegs (see Fig. 5a and b, which is published as supporting information on the PNAS web site).

**ObR:Fc Soluble Chimera Increases the Number of TRegs and Ameliorates Clinical Course and Progression of Relapsing EAE (R-EAE).** Treatment of normal R-EAE-susceptible SJL/J mice with anti-leptin
The percentage of initial body weight in ObR:Fc-treated mice was significantly higher than that of CTR-Ab-treated mice (Fig. 4b and Table 2). On the contrary, control mice showed a more stable body weight loss that was maintained over the disease course (Fig. 4b and Table 2). Finally, CNS inflammatory lesions were also significantly reduced in ObR:Fc-treated mice (Table 2). A significant increase in \( T_{\text{RegS}} \) was observed on d 15 of the disease course in mice pretreated with ObR:Fc (Table 2).

**Discussion**

In this report, we analyze the secretion of leptin in serum and CSF of naïve-to-treatment RRMS patients in correlation with the secretion of IFN-\( \gamma \) in CSF and the percentage of circulating \( T_{\text{RegS}} \). The data presented here provide evidence that a significant increase of leptin secretion occurs in the acute phase of MS and that this event positively correlates with the CSF production of IFN-\( \gamma \). Increased secretion is present in both the serum and CSF of RRMS patients and determines the loss of correlation between leptin and BMI (Fig. 1a). Moreover, the increase of leptin in the CSF is higher than that in the serum (a 5.6-fold increase in CSF leptin vs. a 1.8-fold increase in serum leptin, \( P = 0.001 \), Table 1), possibly secondary to in situ synthesis of leptin in the CNS and/or an increased transport across the blood–brain barrier, upon enhanced systemic production. Indeed, the CSF-leptin/serum-leptin ratio, the CSF-leptin/albumin ratio, and the CSF leptin index all significantly increase in RRMS patients when compared with NIND controls (Table 1).

Recently, gene-expression analysis of Th-1 lymphocytes and active MS lesions in humans revealed elevated transcripts of many genes of the neuroimmunoendocrine axis, including leptin (19, 20). Leptin’s transcript was also abundant in the gene-expression profile of human Th-1 clones, demonstrating that the leptin gene is induced in Th-1 and associated with polarization toward Th-1 responses, commonly involved in T cell-mediated autoimmune diseases such as MS (19, 20). We previously reported in situ leptin secretion by inflammatory T cells and macrophages in active EAE lesions (3). Here, we show that autoreactive MBP-specific T cells from RRMS patients can produce immunoreactive leptin and up-regulate the leptin receptor after activation (Fig. 2a–f), possibly explaining, in part, the increased in situ CSF leptin levels in RRMS patients. Interestingly, both anti-leptin and anti-leptin-receptor blocking antibodies reduced the proliferative responses of hMBP-specific T cell lines (Fig. 2h, j, and l), underscoring the possibilities of leptin-based intervention on this autocrine loop.

Many questions need to be answered about whether and how \( T_{\text{RegS}} \) can regulate autoimmunity in humans. In animal models of autoimmune diseases, the role of \( T_{\text{RegS}} \) has been demonstrated (21). More recently, a reduced function and/or generation of \( T_{\text{RegS}} \) in human autoimmune diseases such as systemic lupus erythematosus, type 1 diabetes, autoimmune polyglandular syndrome type II.

function but, rather, capacity and phenotype compared with TRegs from normal controls. Of the above considerations, we suggest that, in MS, leptin may be the disease but not in patients in the stable phase (22, 23). In view of these data, the frequency in the peripheral blood of naïve-to-treatment RRMS patients were significantly higher than those of healthy controls (Fig. 3 and Table 3). No significant differences in CD3+, CD4+, CD8+, CD19+, and CD3−CD16/CD56+ cells were observed in either study group (Table 3). In addition, our functional data confirmed that, in our experimental conditions, RRMS patients showed a functional TReg deficit, confirming findings previously reported in ref. 15 (Fig. 3d). Administration of exogenous leptin to human TRegs or to suppression assays did not alter hyporesponsiveness and suppressive capacity (Fig. 5 a and b), suggesting that in vitro leptin is not responsible for impaired TReg function. Simple regression analysis showed an inverse correlation between systemic leptin concentrations and TReg in the naive-to-treatment RRMS population (Fig. 3 b and c). These data demonstrate an inverse relationship between leptin and TReg in MS and may account for a reduced generation of TRegs at least early in the disease, in naïve-to-treatment patients. Indeed, we hypothesize that, after therapy, these phenomena may be masked and overcome by therapy-induced effects. In fact, in the case of chronic leptin deficiency, such as in ob/db mice, we found an increased number of circulating TRegs, and similar results were observed in db/db mice. This finding was also confirmed by experiments showing a higher recovery and percentage of TRegs from R-EAE-susceptible SJL/J female mice treated with leptin-blocking ObR:Fc (Fig. 4a). Also, this pretreatment subsequently ameliorated R-EAE onset and progression (Fig. 4b and Table 2). The fact that TReg from db/db mice had a similar suppressive capacity and phenotype compared with TRegs from normal controls (Fig. 6 a-d) suggests that leptin does not affect in vitro suppressive function but, rather, in vivo expansion/proliferation of TReg. Further studies need to address this point. Recent reports have shown increased secretion of serum leptin before relapses in RRMS patients during treatment with IFN-β and the capacity of leptin to enhance in vitro secretion of TNF-α, IL-6, and IL-10 by peripheral blood mononuclear cells of RRMS patients in the acute phase of the disease but not in patients in the stable phase (22, 23). In view of the above considerations, we suggest that, in MS, leptin may be part of a wider scenario in which several proinflammatory soluble factors may act in concert in driving the pathogenic (autoimmune) Th-1 responses targeting neuroantigens (24). Recently, Hafler et al. (15) reported a decreased in the effector function and cloning frequency of TRegs from the peripheral blood of patients with MS. We show here that, in naïve-to-therapy MS patients, not only the functional but also the number of TRegs is affected, and, more importantly, the finding inversely correlates with the concentration of serum leptin. It appears therefore that, early in the disease, the effects on TReg in MS may be different from the effect observed after therapy has been initiated. Regarding the correlation with leptin, it is worth mentioning that strains of mice prone to the spontaneous development of autoimmune diseases, such as nonobese-diabetic (NOD) and IL-2-deficient (IL-2−/−) mice, show reduced frequency of TRegs in the periphery (9) associated with abnormal leptin responses due to increased serum leptin concentrations (disproportionate to fat mass) (25, 26). NOD mice have higher basal serum leptin levels than normal age-, sex-, and fat-matched controls (25). IL-2−/− mice are prone to spontaneous development of inflammatory bowel disease and other autoimmune disorders (26). Whereas in normal mice, serum leptin decreases with fat-mass loss, in IL-2−/− mice there is a paradoxical rise in serum leptin compared with control mice, even after starvation, which reduces serum leptin levels. These data support the hypothesis that a disproportionate response in leptin secretion can correlate with a reduction in the periphery of the TRegs compartment in these two models.

Because of the influence of leptin on food intake and metabolism, the findings reported here underscore the role of molecules at the interface between metabolism and immunity in the control of not only inflammation but also autoimmune reactivity (24, 27). Recently, molecules with orexigenic activity, such as ghrelin and neuropeptide Y (NPY), have been shown to mediate not only effects opposite to those of leptin on the hypothalamic control of food intake but also on peripheral immune responses (28, 29). Indeed, ghrelin blocks the leptin-induced secretion of proinflammatory cytokines by human T cells (28), and NPY ameliorates the clinical course and progression of EAE (29). Given these considerations, we may envisage a situation in which the influences exerted by several metabolic regulators, including leptin, might broadly influence vital functions not limited to caloric tuning but, rather, affecting immune responses and the interaction of the individual with the environment. Although additional studies are needed, our data provide direct evidence of a negative association between leptin secretion and TRegs in the early stages of an autoimmune disease characterized by Th-1 autoreactivity, such as MS.
