Edited by Robert J. Lefkowitz, Duke University Medical Center, Durham, NC, and approved July 22, 2009 (received for review February 17, 2009)

The forebrain cholinergic system promotes higher brain function in part by signaling through the M1 muscarinic acetylcholine receptor (mAChR). During Alzheimer’s disease (AD), these cholinergic neurons degenerate, therefore selectively activating M1 receptors could improve cognitive function in these patients while avoiding unwanted peripheral responses associated with non-selective muscarinic agonists. We describe here benzyl quinoline carboxylic acid (BQCA), a highly selective allosteric potentiator of the M1 mAChR. BQCA reduces the concentration of ACh required to activate M1 up to 129-fold with an inflection point value of 845 nM. No potentiation, agonism, or antagonism activity on other mAChRs is observed up to 100 μM. Furthermore studies in M1−/− mice demonstrate that BQCA requires M1 to promote inositol phosphate turnover in primary neurons and to increase c-fos and arc RNA expression and ERK phosphorylation in the brain. Radioligand-binding assays, molecular modeling, and site-directed mutagenesis experiments indicate that BQCA acts at an allosteric site involving residues Y179 and W400. BQCA reverses scopolamine-induced memory deficits in contextual fear conditioning, increases blood flow to the cerebral cortex, and increases wakefulness while reducing delta sleep. In contrast to M1, allosteric agonists, which do not improve memory in scopolamine-challenged mice in contextual fear conditioning, BQCA induces β-arrestin recruitment to M1, suggesting a role for this signal transduction mechanism in the cholinergic modulation of memory. In summary, BQCA exploits an allosteric potentiation mechanism to provide selectivity for the M1 receptor and represents a promising therapeutic strategy for cognitive disorders.

Basal forebrain cholinergic neurons innervate information processing centers in the hippocampus and cortex to promote attention and memory. During AD, these neurons profoundly degenerate, contributing to cognitive impairment (1). While cholinesterase inhibitors demonstrate the therapeutic potential for boosting cholinergic function in AD, they are limited by tolerability and provide modest benefit, thus there remains a tremendous need for improved therapies (2). Selectively targeting the ACh receptors involved in memory, while sparing receptors involved in other physiological processes, could provide additional efficacy, a widely pursued approach that has yet to lead to new medicines.

ACh signals by activating ligand-gated ion channels (nicotinic receptors) and metabotropic (muscarinic) G protein-coupled receptors (GPCRs) designated M1–M5. Among the mAChRs, M1 is most abundantly expressed in the hippocampus, cortex, and striatum, and localizes to postsynaptic membranes (3), where it signals via Gq/11 G-proteins to phospholipase C and through other G-proteins to additional signaling systems (4,5). M1 regulates several ion channels including KCNQ inwardly rectifying K+ currents, voltage-gated calcium channels, and NMDA receptors (4–9). Thus M1 could mediate much of the cognitive effects of ACh. Supporting this hypothesis xanomeline, an M1/M4 preferring agonist, improved cognition and behavior in AD patients but was not tolerated due to unwanted cholinergic effects (10). Additional studies suggest that M1 activation could slow AD progression by reducing Aβ42 peptides (11). Thus a drug that activates M1 could potentially improve cognition while over time slowing the progression of the disease. Unfortunately, conservation of the ACh binding site has precluded the discovery of selective agonists.

Many GPCRs, including mAChRs (12), have allosteric binding sites bound by small molecules that activate the receptor in the absence of ligand (allosteric agonist) or enhance the response to native ligand (positive allosteric modulator) (13). As allosteric sites are theoretically under less evolutionary constraint, targeting them affords opportunities for selectivity. This concept was demonstrated by the M1 allosteric agonist TBPB (14) and a collection of relatively selective positive allosteric modulators (15). Here we describe BQCA [1-(4-methoxybenzyl)-4-oxo-1,4-dihydroquinoline-3-carboxylic acid], an orally available drug-like molecule that regulates M1, and represents a promising therapeutic strategy for cognitive disorders.

Materials and Methods

Identification of BQCA. To identify M1 potentiators a screen was conducted on ~1,000,000 compounds (see Materials and Methods). CHO cells stably expressing human M1 and an NFAT-responsive β-lactamase reporter to monitor Gq activation were treated with the EC15 of acetylcholine (15 nM) plus 6.23 μM of test compound. Compounds that increased signal more than 3 standard deviations from the mean, but had no effect in the absence of ACh, were selected for confirmation. This strategy yielded BQCA (Fig. L4), which is unrelated to other muscarinic ligands. BQCA alone had no effect on calcium mobilization up to 10 μM but increased ACh potency 128.8 ± 20.1-fold at 100 μM (n = 12) (Fig. 1B), with an inflection point (IP) value when potentiating 3 nM ACh of 845 ± 27 nM (n = 225) (Fig. 1C). Similar potentiation was observed in CHO cells stably expressing rhesus, dog, rat, or mouse M1 [IP = 300 ± 30 (n = 25), 300 ± 23 (n = 20), 330 ± 24 (n = 26), 210 ± 11(n = 32), respectively]. At 100 μM BQCA activated M1 in the absence of ACh to an approximate 50% maximal response (Fig. 1C). BQCA was then tested up to 100 μM on the other human mAChRs. For M2 and M3, CHO cells stably expressed the mutant m1A cluster.

This article contains supporting information online at www.pnas.org/cgi/content/full/0900903106/DCSupplemental.
selectivity was caused by differences in M1 expression, \[^{3}H\]-NMS selectivity. Addressed the possibility that selectivity over M2 and M4 was due to enzyme assays at 10 mmol/L phosphat (IP3) metabolism in neurons by activating endogenous M1, brain concentrations approximating its potency (Fig. S3). Thus carboxylic acid that when dosed orally at 10 mg/kg in rats achieves the artificial G protein. BQCA had no effect on \[^{35}S\]-GTP CHO cells expressing M2 or M4 and only endogenous G-proteins activate phospholipase C, permitting direct comparison between G protein Gqi5 (16), which allows these Gi-coupled receptors to be selective for M1. To rule out the possibility that selectivity over M2 and M4, which are Gi coupled and do not normally elicit a calcium response, a permissive recombinant G protein, Gqi5, was expressed in those cell lines. BQCA had no effect on the other human mAChRs at the highest concentrations tested (100 \(\mu\)M). Data shown are representative of 3 independent experiments. (C) In situ hybridization for c-Fos (Top) and arc (Bottom) RNAs in sagital sections of wild-type or M1 \(-/-\) mice brains taken 1.5 h after oral dosing with 15 mg/kg BQCA or vehicle (saline).

M3, or M5 receptors. To determine if BQCA is selective over endogenous neuronal mAChRs, primary mouse cortical neurons were treated with vehicle or BQCA (10 \(\mu\)M) for 10 min then ACh for 30 min, and levels of the IP3 metabolite IP1 were measured by homogeneous time resolved fluorescence (HTRF). As expected ACh increased IP1 as evidenced by reduction in HTRF signal; this effect was potentiated 23.3 \(\pm\) 3.0-fold \((n=4)\) by 10 \(\mu\)M BQCA (Fig. 2B). When cultures from M1 \(-/-\) mice were analyzed, ACh increased IP1 levels but BQCA showed no effect, confirming selectivity for M1.

**Selectivity in Vivo.** To evaluate the effects of BQCA on c-fos and arc RNA induction, markers of neuronal activation, mice were treated orally with 15 mg/kg BQCA and brains were collected 90 min later.

**G protein Gqi5 (16), which allows these Gi-coupled receptors to activate phospholipase C, permitting direct comparison between receptor subtypes. No effect was detected on M2–M5, indicating >100-fold selectivity (Fig. 24). To rule out the possibility that selectivity was caused by differences in M1 expression, \[^{3}H\]-NMS binding to membrane preparations was measured and revealed that levels were comparable (see Materials and Methods). Next we addressed the possibility that selectivity over M2 and M4 was due to the artificial G protein. BQCA had no effect on \[^{35}S\]-GTP\(_{\gamma}\)S binding, which measures the recruitment of activated G-proteins, in CHO cells expressing M2 or M4 and only endogenous G-proteins (Fig. S1). BQCA had no activity in >300 radioligand binding and enzyme assays at 10 \(\mu\)M (see Materials and Methods) and did not significantly potentiate eight other class A GPCRs at 37.5 \(\mu\)M (Fig. S2). BQCA is a low molecular weight (331.3 Da) quinolone carboxylic acid that when dosed orally at 10 mg/kg in rats achieves brain concentrations approximating its potency (Fig. S3). Thus BQCA is a drug-like molecule that potentiates M1 with >100-fold selectivity.

**Selectivity on Native Receptors.** ACh increases inositol triphosphate (IP3) metabolism in neurons by activating endogenous M1, or orally with 15 mg/kg BQCA and brains were collected 90 min later.
for in situ hybridization. In wild-type mice, BQCA induced c-fos and arc RNA in the cortex, hippocampus, and cerebellum; arc was also elevated in the striatum (Fig. 2C). In contrast BQCA had no effect in M1<sup>−/−</sup> mice. We then assessed the phosphorylation of ERK in wild-type and M1<sup>−/−</sup> mouse cortex and hippocampus. ERK phosphorylation is a common downstream signaling event that functions in synaptic plasticity and memory (17). In wild-type mice, 15 mg/kg BQCA dosed orally increased the ratio of phosphoERK (pERK) to total ERK as revealed by western blot (28% increase, n = 6, P = 0.007, one-way ANOVA, Fig. S4). There was no effect on total ERK levels or cortical pERK. The increase in pERK was absent in M1<sup>−/−</sup> mice. 

**Mechanism of Potentiation.** We next determined if BQCA interacted with the ACh binding site. In radioligand competition assays 100 µM BQCA had no effect on the binding of the ACh-site directed antagonist [3H]-N-methyl-scopolamine (NMS) to hM<sub>1</sub>-CHO membranes (Fig. 3A). Instead BQCA reduced the concentration of ACh required to displace [3H]-NMS 45-fold at 10 µM (Fig. 3B), and enhanced [35S]-GTPγS binding to hM<sub>1</sub>-CHO membranes in response to ACh 32-fold at 10 µM (Fig. 3C). Using Schild analysis, BQCA decreased the concentration of ACh required to displace [3H]-NMS across all concentrations tested, but did not change the dose ratio, indicating that it does not exhibit cooperativity with ACh under equilibrium binding conditions (Fig. S5). Therefore BQCA binds an allosteric site to enhance the binding and efficacy of ACh. 

**Interaction with the Extracellular Domain.** Molecular modeling was used to dock BQCA into human M1. A potential extracellular binding site was identified near amino acids Y179 and W400. These two residues and their immediately adjacent amino acids are 100% conserved in rhesus, dog, rat, and mouse M1. Instead whereas W400 is, E401 is not conserved and only M1 possesses a negatively charged residue at this position (Fig. 3D). We mutated Y179 and W400 to alanine; both mutations abrogated the effect of BQCA without affecting ACh (Fig. 3E). These two residues and their immediately adjacent amino acids are 100% conserved in rhesus, dog, rat, and mouse M1. In contrast Y179 is not well conserved in other human mAChRs, and although whereas W400 is, E401 is not conserved and only M1 possesses a negatively charged residue at this position (Fig. 3F). Thus sequence diversity in the regions near Y179 and W400 could underlie BQCA selectivity.
Fig. 4. Physiological effects of BQCA. (A) Contextual fear conditioning. On day one animals received 0.3 mg/kg scopolamine or BQCA administered IP at the indicated doses before being introduced to a novel environment and receiving two foot shocks. Twenty-four hours later animals (n = 12–16/group) were reintroduced to the environment and freezing measured by automated detection equipment. Shown is mean percent of time freezing (± SEM). Data are representative of four experiments. *, Different from vehicle; #, different from scopolamine + vehicle (P < 0.05, Dunnett test). (B) Increased cerebral blood flow in anesthetized rats in response to BQCA. Data were averaged over 1 min at the indicated time points (A–C) and is expressed as mean percent change from baseline ± SEM. (n = 4 animals). *, Significantly different from baseline, *P < 0.01, repeated measures ANOVA, t test.

Contextual Fear Conditioning. To examine the role of M1 in memory we measured contextual fear conditioning (CFC) in mice. This task requires the hippocampus (18) where M1 is highly expressed. Subjects were introduced to a novel environment where they received an aversive stimulus (foot shock). The next day the animal exhibited freezing behavior, indicative of fear, if it associated the aversive stimulus with the environment. Scopolamine, a nonselective muscarinic antagonist, was dosed 30 min before introduction to the novel environment to block formation of this association (19) (Fig. 4A). BQCA was co-dosed at 5, 10, 15, and 20 mg/kg IP with scopolamine on training day and had no effect on freezing behavior at that time. When animals were reintroduced into the test chamber those given scopolamine previously showed marked reduction in freezing compared to controls. However animals that had been co-dosed with BQCA at 15 or 20 mg/kg had no scopolamine deficit (P < 0.05, ANOVA, Dunnett test). This experiment was repeated with structurally distinct derivatives of BQCA that are also >100-fold selective for M1 with similar results. Thus BQCA prevents scopolamine-induced memory deficits in CFC.

Cerebral Blood Flow. ACh promotes cerebral blood flow (CBF) (20) and M1 is expressed in cortical neurons and endothelial cells (21), however a role for M1 in CBF has not been defined. BQCA, but not vehicle, intravenously infused into anesthetized rats at 10 mg/kg caused a sustained increase in CBF by 20.5 ± 0.9% as measured by laser Doppler flowmetry (F1,207 = 14.1; *P = 0.005) (Fig. 4B).

Fig. 5. Allosteric agonists do not reverse scopolamine deficits in contextual fear conditioning or recruit β-arrestin. (A) Effects of TBPB at 10 and 30 mg/kg (mpk) in contextual fear conditioning. Shown is mean (n = 16/group) percent of time exhibiting freezing behavior ± SEM. *, Different from vehicle alone (P < 0.05, Dunnett test). Experiment was repeated twice with similar results. (B) TBPB and AC-42 (allosteric agonists, top circle) do not significantly recruit β-arrestin to hM1 compared to BQCA and 8 related allosteric potentiators (allosteric potentiators, bottom circle). Potencies (IP) for these compounds in calcium mobilization as measured by FLIPR (x axis) were compared to β-arrestin recruitment as measured by enzyme complementation (y axis). In both experiments, CHO cells stably expressing hM1 were used, for β-arrestin hM1 is fused to a portion of β-galactosidase while a complementary β-galactosidase fragment is fused to β-arrestin. Thus β-galactosidase activity is an indirect measure of β-arrestin recruitment. Values along the dashed lines indicate that no inflection point in the slope was observed at the highest concentrations tested (representative dose–response curves are in Fig. S8C). Note that the allosteric potentiators show a correlation between calcium mobilization and β-arrestin recruitment whereas for the allosteric agonists IP values were only measurable in calcium mobilization.

Effects on Sleep. The cholinergic system modulates wakefulness and the onset of REM sleep (22, 23). To assess the role of M1 in sleep, rats were dosed with BQCA at 10 mpk IP 30 min before the beginning of the light (inactive) cycle for seven days. Electrocor-ticogram and electromyogram activities were recorded and the time spent in active wake, light sleep, REM, and delta sleep were averaged in 30 min epochs across 7 days of testing. Over the first 90 min of the light phase BQCA increased the time spent in active wake and light sleep while concomitantly decreasing delta sleep (P < 0.001, Student’s t test) (Fig. S6). By 120-min sleep patterns between BQCA-treated and control animals were similar and no lasting effects where observed.

Allosteric Agonists Exhibit Differential Efficacy. We then compared the activities of BQCA to TBPB, an M1-selective allosteric agonist that has anti-psychotic-like activity in rats (14). Like TBPB, BQCA at 10 and 30 mg/kg IP repressed amphetamine-induced locomotion in mice (Fig. S7A). However TBPB did not reverse the scopolamine deficit in CFC at 10 or 30 mg/kg IP (Fig. 5A); and similarly the allosteric agonist AC-42 was without effect at 3, 10, and 30 mg/kg (12) (Fig. S7B). To explore this difference we measured recruitment of β-arrestin, which mediates GPCR internalization and second messenger signaling (24). CHO cells expressing hM1 fused to a portion of β-galactosidase and β-arrestin fused to a complementary fragment of β-galactosidase (25) were treated with TBPB, AC-42, or ACh ± BQCA or eight BQCA analogs. Recruitment of
ACh activity from an allosteric pocket (Fig. 3). Molecular modeling BQCA does not interact with the ACh site but instead enhances despite the therapeutic potential of M1, high selectivity against other assays. In the absence of M1 BQCA does not enhance ACh-mediated inositol phosphate metabolism or induce c-fos or arc RNA or ERK phosphorylation in the brain (Fig. 2 and Fig. S4). BQCA does not interact with the ACh site but instead enhances ACh activity from an allosteric pocket (Fig. 3). Molecular modeling combined with site-directed mutagenesis identified a potential extracellular interaction site conserved in M1 that diverges in other mAChRs (Fig. 3). Interestingly Y179, one of the residues required for BQCA activity, corresponds to Y177 in M2, which is in a common site critical for multiple allosteric agonists (26). Thus probing this region further could improve our understanding of allosteric modulation.

We used BQCA to explore the function of M1 in brain function. BQCA promotes the learned association of a novel environment with an aversive stimulus, a task dependent on the hippocampus and sensitive to the anti-muscarinic scopolamine (Fig. 4). Selectively sensitizing M1 with BQCA fully overcomes the anamnestic effects of scopolamine in this model. These results contrast with data in M1−/− mice (27) and with an M1 selective antagonist, VU0255035 (28). In the former study the M1−/− mice showed no deficit in CFC, and in the latter study VU0255035 reduced pilocarpine-induced seizures in rats, which requires M1 (29), but did not interfere with CFC. Together these data suggest that deletion or inhibition of M1 does not interfere with this form of memory. However our data indicate that M1 activation during acquisition promotes memory, perhaps indicating that M1 is not required for memory formation in CFC, but rather reinforces it by stimulating other receptor signaling systems such as the NMDA receptor (6). Based on prior work (30) M1 expressed in CA3 hippocampal neurons may be specifically involved in this positive modulation of memory.

We found that BQCA enhanced CBF (Fig. 4), a function of ACh attributed to M1 based on receptor localization and knockout mouse experiments (31, 32). Our data indicate that M1 also regulates CBF perhaps via neurovascular coupling. The cholinergic system also modulates sleep; ACh levels are elevated in the cortex and hippocampus during wakefulness and REM sleep relative to slow wave delta sleep (33). When doses before the onset of sleep BQCA increased wakefulness and inhibited delta sleep without significant lasting effects (Fig. S7). This observation is consistent with M1 promoting arousal and suggests that ACh levels decline during slow wave sleep in part to reduce M1 activity.

Since allosteric ligands of GPCRs can selectively modulate some, but not all, available second messenger signaling systems (34) we compared BQCA to the allosteric agonists TBPB and AC-42. Both BQCA and TBPB inhibit amphetamine-induced locomotion in mice (14 and Fig. S7), suggesting that they modulate striatal dopaminergic activity. In contrast neither TBPB nor AC-42 reversed scopolamine deficits in CFC (Fig. 5 and Fig. S7). A potential reason for this difference is that these compounds do not efficiently induce β-arrestin recruitment as measured by enzyme complementation (Fig. 5). Other studies show that AC-42 does not activate all G-proteins coupled to M1 (35), together suggesting that these allosteric agonists may exhibit ligand bias (36), the propensity to activate a subset of signaling pathways presumably by stabilizing unique receptor conformations. Since β-arrestins couple M1 to diacyl glycerol kinases (24) and likely play other signaling functions, it will be interesting to identify β-arrestin-dependent responses triggered by BQCA.

In summary we identified a highly selective positive allosteric modulator of the M1 muscarinic receptor. This compound will allow for further understanding of allosterism at GPCRs, insight into the function of M1, and potentially a class of therapies for diseases involving impaired function of the central cholinergic system.

**Materials and Methods**

**Materials.** Reagents were from Sigma unless noted, and animals were from Taconic Farms. Procedures were approved by the Institutional Animal Care and Use committee (IACUC) in accordance with the National Institutes of Health Guide for the Care and Use of Laboratory Animals. Chrm1−/− animals were provided by Dr. Neil Nathanson (37).

**Data Presentation.** Experimental values are the mean of n independent determinations ± SEM unless otherwise indicated.

**High-Throughput Screening.** Using an automated screen for Gq activation by GPCRs (38), 2 × 106 cells/well of CHO cells expressing human M1, and an NFAT-responsive β-lactamase reporter were plated into 3,456 well plates and treated with 15 nM ACh plus 6.25 nM BQCA, TBPB, or vehicle for 4 h before adding CC4-AM (Invitrogen), to detect β-lactamase activity.

**Fluorometric Imaging Plate Reader (FLIPR).** CHO-NFAT cells expressing human mAChRs or rhesus, dog, mouse, or rat M1 (in CHO-K1, ATCC) were plated (25,000 cells/well) in clear-bottomed polyd-lysine (PDL)-coated 384-well plates in growth medium using Labsystems Multidrop. Receptor expression levels for the human lines were measured by radioligand binding and were M1 (0.70 ± 0.03), M2 (3.22 ± 0.08), M3 (0.53 ± 0.04), M4 (1.61 ± 0.09), and M5 (0.80 ± 0.07) pmol/mg protein (n = 3). Cells were grown overnight 37°C/6% CO2 washed 3 × 100 μL assay buffer (Hanks’ balanced salt solution 20 mM HEPES/5.25 mM probenecid/0.1% BSA) then incubated with 1 μM Fluo-4.a.m. (Invitrogen) 1 h at 37°C/6% CO2. Extracellular dye was removed and Ca2+ was measured with a FLIPR384 fluorometric imaging plate reader (Molecular Devices) during incubation with compound 4 min followed by 4 min with the EC50 of ACh.

**IP1.** Cortical hippocampal neurons from embryonic day 15–16 wild-type or Chrm1 (M1)−/− mice were plated (70,000 cells/well) in PDL 96-well white plates and maintained 9 days. IP1 levels were measured using HTRF (Cisbio Bioscays) using Envision (Perkin-Elmer) following 10-min incubation with BQCA then 30 min with ACh. Ten mM LiCl was added to block degradation of inositol phosphates.

**β-Arrestin.** The hM1AChR PathHunter CHO cells (DiscoverX) stably expressing two fragments of β-galactosidase, one fused to M1 and the other to β-arrestin, were treated with ligand and β-galactosidase complementation was monitored by PathHunter Detection reagent and read on a ViewLux (Perkin-Elmer).

**Binding Assays.** Competition binding reactions used 25 μg human M1 CHO membrane protein (Perkin-Elmer), test compounds or vehicle, and 0.15 nM [3H]NMS in 96-well deep-well plates. Binding reactions (30°C 2 h) were terminated by rapid filtration. Nonspecific binding was determined by adding 10 nM of test compound for 4 h before adding CCF4-AM (Invitrogen), to detect β-lactamase activity.

**Counterassays.** BQCA was tested in duplicate (10 μM) for activity or radioligand displacement on >300 enzymes and receptors using commercially available assays (MDS Pharma). For potentiation of class A GPCRs, BQCA (37.5 μM) was analyzed ± agonist by FLIPR in CHO cells stably expressing the receptors using GPCRprofiler, details are available from the manufacturer (Millipore).

**Molecular Modeling.** Mutations were made by site-directed mutagenesis and sequence confirmed before transient transfection into CHO cells. Maximal bind-
Immediate Early Gene Induction. Wild-type or Chrm1 (M1)−/− mice were individually housed and desensitized by handling 5 separate times before the experiment. Mice (n = 5/group) received 15 mg/kg BQCA in 5% beta-cyclodextrin/saline IP. After 1.5 h animals were euthanized; in situ hybridization has been described in detail (41).

ERK Phosphorylation. Adult (4–6 week) male mice (n = 6) were dosed with 15 mg/kg PO BQCA in sterile water or with vehicle alone and 1 h later cortical and hippocampal samples were collected. Homogenization was performed on ice in 0.3 M sucrose/1 mM HEPES/1 mM MgCl2/1 mM EDTA/1 mM NaHCO3 (pH 7.4) supplemented with protease and phosphatase inhibitors. Thirty µg total protein was resolved on 10% SDS gels and probed with rabbit polyclonal anti-p44/p42 MAPK (T202/Y204) or mouse monoclonal anti-p42 MAPK (3A7) (Cell Signal Technologies). Immunoblots were quantitated on a Li-Cor Odyssey infrared imager (Li-Cor Biosciences).

Contextual Fear Conditioning. On day one 10-week-old experimentally naïve male B6SJL mice (n = 12–16/group) were dosed IP with BQCA in 5% beta-cyclodextrin and/or 0.3 mg/kg scopolamine in 0.9% saline 30 min before placement into a chamber (MED-VFC-M, Med Associates) for 2 min before 2 tone-footshock pairings (3 kHz, 85 dB tone for 30 s co-terminated with a 0.5 mA, 1 s shock) 2 min apart. Mice were removed to their home cage 30 s after the last pairing. Twenty-four hours later mice were placed into the same chamber and freezing was measured by Video Freeze (Med Associates).

Cerebral Blood Flow. Six- to eight-week-old male Sprague-Dawley rats were anesthetized with urethane (1 g/kg IP). Depth of anesthesia was monitored by toe pinch; supplemental urethane (10% of initial dose) was given to achieve deep anesthesia. Body temperature was kept at 37 °C via a heating pad and rectal temperature feedback probe. A femoral artery was cannulated with PE50 tubing to record arterial pressure and heart rate via a pressure transducer (ADInstruments); the femoral vein was cannulated for drug infusion (20 µL/min). Animals were placed in a stereotactic frame and a midline incision exposed the skull. A burr hole was drilled over the frontal cortex (1.0 mm anterior and 4.0 mm lateral to bregma) leaving the dura intact. A laser Doppler probe connected to a data acquisition system (PowerLab 8/30, ADInstruments) was placed over the hole. CBF recordings began after MAP, HR and CBF were stable for 15–20 min. Data are presented as percent increase over resting CBF.

Sleep Electroencephalography (EEG). Sleep was evaluated in adult male Sprague-Dawley rats (age 3–8 months) chronically implanted with telemetric physiological monitors recording electrocorticogram and electromyogram activities as described (42). Dosing was 30 min before lights on for 7 days in a crossover experiment.

Amphetamine-Induced Locomotor Activity. Six week old male B6SJL mice (n = 12) were dosed IP with the indicated dose of BQCA and placed into standard open field boxes, equipped with infrared motion sensors for 20 min. They were then given 2.5 mg/kg amphetamine then returned to the open field box and tracked for additional 40.25 min.

ACKNOWLEDGMENTS. We thank Dr. Neil Nathanson, University of Washington, for providing the M1−/− mice. We thank the following for technical support and scientific input: Robert Breese, Michele Crouthamel, Pierre Mallorca, Christine M. Ogaki, Bhaskar N. Roy, Jonathan Schneeweis, Mark Bilodeau, Samuel Graham, George Hartman, Kenneth Koblan, Kenneth Koeplinger, John Renger, Sethu Sankaranarayanan, Adam Simon, Charles Thompson, and Joseph Vaccara.
