Edited by David B. Wake, University of California, Berkeley, CA, and approved February 2, 2010 (received for review January 8, 2010)

Although populations of amphibians are declining worldwide, there is no evidence that salamanders occupying small streams are experiencing enigmatic declines, and populations of these species seem stable. Theory predicts that dispersal through multiple pathways can stabilize populations, preventing extinction in habitat networks. However, empirical data to support this prediction are absent for most species, especially those at risk of decline. Our mark-recapture study of stream salamanders reveals both a strong upstream bias in dispersal and a surprisingly high rate of overland dispersal to adjacent headwater streams. This evidence of route-dependent variation in dispersal rates suggests a spatial mechanism for population stability in headwater-stream salamanders. Our results link the movement behavior of stream salamanders to network topology, and they underscore the importance of identifying and protecting critical dispersal pathways when addressing region-wide population declines.

amphibian decline | dendritic ecological network | stream salamander | plethodontidae | movement

Despite the implications of spatial structure for the evolution of dispersal and resulting dynamics (1, 2), quantifying movement in real population networks has proven tremendously difficult (3). Of particular importance are specific, rarely observed dispersal pathways that are vital to network dynamics (2, 4), species distributions (5, 6), and population stability (7, 8). In theoretical network models, the propensity for small amounts of dispersal through multiple pathways is especially critical for population stability and metapopulation persistence (4, 9). However, empirical data for such dispersal probabilities in many organisms, particularly amphibians (10), are lacking.

Large-scale, enigmatic declines of amphibians have been documented worldwide (11), but existing data on headwater-stream salamanders in the Appalachian Mountains of eastern North America suggest stable populations. Estimated local extinction rates are near zero for species living in these habitats, and there are significantly smaller population fluctuations (in both change in population size and variance in population sizes) than for either pond- or river-breeding amphibians (12). Given ongoing modifications to the geometry and dynamics of riverine networks (13, 14) and the potential for large-scale changes in stream-network structure because of climate and landscape change (15), understanding the link between dispersal and network geometry may be crucial to addressing future impacts on demography, evolution, and community assembly in stream amphibians and other freshwater species.

The hierarchical geometry of stream systems distinguishes these ecological networks from other spatially structured habitats (16). In such dendritic networks, dispersal can follow two pathways: along network branches (within-network movement) or overland between branches (out-of-network movement). Variation in dispersal pathways may be related to species- or age-specific habitat associations, and may have strong effects on population persistence, evolutionary dynamics, and patterns of community composition.

In species that are restricted to network branches, dispersal is constrained by network structure (17), and consequently, population stability and local extinction risk are predicted to be highly sensitive to network position and direct connections among occupied branches (18). A capacity for overland dispersal between branches is predicted to increase population stability and decrease extinction risk significantly by providing periodic connectivity among spatially isolated reaches (4, 9). In the only reported decline that we could find in a stream-associated plethodontid (19), populations that were close in overland distance showed high genetic divergence, indicating that the overland movement pathway was not used in this population.

Because habitat conditions vary along the stream continuum (20), dispersal between branches at the same hierarchical level also reduces the probability of settlement in new and inhospitable habitat. Furthermore, dispersal distances between branches are generally shorter by overland routes than along stream corridors, especially in the uppermost reaches of river networks (i.e., the headwaters). This suggests that headwater specialists, including many amphibians and invertebrates, should evolve upstream-biased movement and overland dispersal strategies (21, 22).

Plethodontids (the family of lungless salamanders) have their greatest species diversity in upland, headwater areas of North and Central America, including the Appalachian Mountains (23). Stream-associated plethodontids have a complex life cycle (24) where aquatic larvae metamorphose into juveniles that, like adults, can be largely terrestrial. This life cycle allows the possibility of different movement behavior in each age class. In members of the genus Desmognathus, a dominant genus of plethodontids, the larval stage is brief and unlikely to allow significant dispersal within a stream network, but large postmetamorphic animals may disperse overland with less desiccation risk. Theoretical models and empirical data make clear that juveniles are more likely to disperse than adults in most species, reducing both kin competition and the potential for inbreeding (25). We would, therefore, expect postmetamorphic juvenile salamanders to have higher dispersal probabilities than adults.

We combined theory on spatially structured networks, particularly dendritic networks, with empirical observations of marked animals to test the following predictions: (i) stream salamanders use multiple movement pathways, both within-stream dispersal (the primary pathway) and overland dispersal (the secondary pathway), (ii) juveniles have higher dispersal probabilities than other life stages, and (iii) dispersal through these multiple pathways stabilizes stream salamander populations. Specifically, with data from 491 D. fuscus and 2,043 D. fuscus.
D. monticola that were individually marked over a 2-year period in stream networks in Virginia, we directly quantified within-stream and overland dispersal probabilities. To investigate the consequences of the observed dispersal probabilities in dendritic metapopulations, we then conducted a simulation study in a fractal branching network of 15 habitat patches under different annual per-patch extinction probabilities.

**Results**

We first tested if *D. fuscus* and *D. monticola* differed in their relative movement behavior. For example, one species may prefer to move along the stream channel, whereas the other may make overland movements. A likelihood ratio test indicated little support for species-specific differences in movement rates ($\chi^2 = 4.22; df = 2; P = 0.121$), although a model specifying a different overall propensity for movement for each species provided a better fit to the data than one that estimated a single rate for each pathway ($\chi^2 = 15.609; df = 3; P = 0.001$). Investigation of the model-averaged point estimates for each dispersal probability indicated that *D. fuscus* has higher probabilities of moving via any given pathway than *D. monticola* (Fig. S1), although the estimate of the effect has a large SE. The results from these tests indicate that the movement ecology of the two desmognathine salamanders is similar and lends support to our hypothesis that the movement ecology of these species is related to their life-history characteristics. We, therefore, combined the data from both species for the remainder of our analysis. Two of five candidate models representing our hypotheses about stream salamander dispersal were supported by the data and had a combined model weight of 93% (Table 1). We calculated model-averaged estimates of the transition probabilities ($\psi^t$) that were not conditional on a single model in the set (26).

Newly metamorphosed juveniles (i.e., those individuals that were larvae in time $t−1$) had the highest probabilities of dispersing to other stream reaches; both a strong upstream bias in dispersal and a moderate probability of dispersing overland between reaches were apparent (Fig. L4). Postmetamorphic juveniles (i.e., those individuals that were juveniles in time $t−1$) had higher site fidelity and lower probabilities of dispersing between reaches. However, like newly metamorphosed juveniles, they were more likely to move upstream than downstream and had a nonnegligible probability of dispersing overland to an adjacent reach (Fig. 1B). Adults exhibited the highest site fidelity with dispersal probabilities near 0 (Fig. 1 C and D).

We were not able to explicitly separate overland from within-network movements between the uppermost reaches of our stream pairs. However, to travel between the two uppermost reaches along the stream corridors, an individual would have to survive and move first from the upper to the lower reach ($\Delta_1 = \psi_{upper1-lower} \cdot \delta_{upper1-lower}$) and then survive and move from the lower reach to the adjacent upper reach ($\Delta_2 = \psi_{lower-upper} \cdot \delta_{lower-upper}$). Across all age classes, this sequence of probabilities ($\Delta_1 \cdot \Delta_2 = 0.0001$) is much lower than the overland movement probability calculated for the same two time periods ($\psi_{upper-lower} = 0.00474$): an individual could either survive and remain in the uppermost reach ($\psi_{upper-upper} = \delta_{upper-upper}$) or vice versa. This suggests that movement between upper reaches along stream corridors is possible, but that such movements are of minor significance relative to overland movements.

Comparing our observed movement rates with the results from the simulation model (Fig. 2), we found that our data support general theory predicting increased population stability in networks with even a small amount of overland dispersal (2, 9). This effect is most pronounced when extinction rates are low. Under markedly increased extinction rates (as might be expected given an epizootic) (27), populations are unlikely to persist, even with relatively high rates of dispersal.

**Discussion**

Using individually marked animals across multiple life stages, we quantified the specific dispersal pathways used by stream salamanders in headwater-stream networks, and we show that route-dependent variation in dispersal rates may be a spatial mechanism enhancing population stability in these species. High rates of overland dispersal in newly metamorphosed juveniles were particularly striking, especially considering that our surveys were conducted during two of the driest summers in recent history. Although desiccation risk may limit terrestrial activity of juvenile animals (28, 29), episodic afternoon thunderstorms (common in mountain systems) may provide windows of opportunity for overland movement. The existence of such temporarily varying habitat conditions underscores the importance of using marked animals to identify specific dispersal pathways.

Dispersal is a key component of population dynamics (30). In stream networks, there are two dominant pathways for dispersal: within-network dispersal or overland dispersal between habitat

Candidate model set showing constraints used on the transition probability parameter ($\psi^t$), including the $\Delta$AICc values and associated model weights (w) for each model. All models included the most parsimonious structure on $\psi$ (stream reach, temporary removal pass (1–3), and sampling month) and $\delta$ (age class and sampling month), and we estimated a separate movement probability for each type of age transition. We used model-averaging calculations to combine estimates from each model using their associated model weights (w) to provide an estimate of the predicted effect (Fig. 1).
Within-network dispersal has been described for a number of stream-associated organisms [e.g., invertebrates (31), fish (32, 33), and salamanders (34, 35)]. In contrast, overland dispersal is poorly characterized for most species, although studies have documented this dispersal pathway in stream invertebrates (22, 36), observed short-distance overland movements in stream salamanders (35), and inferred overland dispersal in studies of genetic relatedness in stream salamanders (17) and invertebrates (37). The dendritic architecture of headwater-stream networks may influence the dispersal pathways used by organisms living in these networks, which may contribute to these striking differences in population trajectories among amphibian taxa (16). In spatially structured habitat networks, propensities for movement along specific pathways may represent evolutionary adaptations to network structure. We suggest that headwater specialists may have evolved overland dispersal as one strategy for persistence in dendritic habitat networks. This hypothesis is supported by our finding that the two Desmognathus species did not differ in their relative use of the overland versus within-stream movement pathways.

The observed rates of upstream and overland dispersal by juvenile salamanders support our prediction that the dendritic structure of stream systems affects the basic movement behavior of headwater specialists (16). Our data represent direct observations of salamander movement in headwater networks and identify a mechanism for increased occupancy and abundance in these systems (17, 38, 39). Within the restrictive spatial structure of dendritic networks, the use of multiple dispersal pathways is critical to population stability (2, 9). Understanding the population-level mechanisms for amphibian decline and persistence may require similarly detailed investigation into the movement ecology of these animals, with special attention to the pathways and life stages of dispersal. Our study was conducted in continuous forest habitat and designed to describe the movement ecology of headwater-stream salamanders in undisturbed habitat. Understanding how different types of habitat in the terrestrial matrix may influence movement rates would be a logical next step, especially because terrestrial habitat loss and alteration are a major threat to amphibian population persistence (40).

The magnitude and directional bias of movement has context-dependent effects on population dynamics (25). For example, low-to-moderate rates of dispersal can increase population stability and metapopulation persistence (8, 41), whereas higher rates of dispersal can synchronize populations (42–44), potentially increasing extinction risk (45, 46). Our results agree with theoretical models showing positive effects of low-to-moderate dispersal rates, but they also expand on these models by showing the importance of specific pathways of dispersal to population dynamics (2, 4, 44).

Overland dispersal may be a natural component of an organism’s movement ecology (22, 31) or may result from anthropogenic actions. These actions can be intentional (e.g., translocation as part of a species’ recovery plan) (47) or accidental (e.g., introduction of an invasive species) (48). We find that the frequency of overland dispersal interacts with within-stream dispersal and local extinction probability to influence population persistence (Fig. 2). Specifically, our results suggest that freshwater species that cannot
make overland movements, such as fish, sessile invertebrates, and mollusks, may benefit disproportionally from overland translocations (i.e., increasing the y-axis value in Fig. 2). Likewise, eliminating these overland connections may be especially crucial to slowing the spread of invasive species. More broadly, our results underscore the importance of identifying and protecting critical dispersal pathways when addressing region-wide population declines such as those observed in many amphibians.

Methods

Field Data Collection. In each of two pairs of confluent streams in Shenandoah National Park, Virginia, we individually marked salamanders of all age classes in three 40-m reaches that were separated by 350–500 m either along the stream corridor or across terrestrial habitat (Fig. 1). All research was performed under appropriate Animal Care and Use Committee approval (University of Maryland-06-01-15). Each reach was surveyed using three temporary removal passes in May, June, July, and September of 2007 and 2008.

Age Classification. Individuals were classified into three ages: larval, juvenile, and adult. Animals were assigned to either the juvenile or adult age class based on the distribution of sizes: D. fuscus individuals were classified as adults when their snout-to-vent length exceeded 36 mm, and D. monticola individuals were classified as adults when their SVL exceeded 45 mm (49–51).

Multistate Modeling of Individual Capture Histories. Using multistate mark-recapture modeling (52), we estimated the probabilities of within-network versus overland, out-of-network movements. We used the Huggins formulation of the closed, robust-design, multistate model implemented in program MARK (53) to estimate survival ( \( \psi \) ) and capture probabilities ( \( p_{ij} \) ) at each site and transition probabilities ( \( \psi(\kappa) \) ) among age-reach states. The survival probability is the probability that an animal alive at time \( t \) survives to time \( t + 1 \) and remains in the study system (i.e., does not die or permanently emigrate), whereas the capture probability ( \( p_{ij} \) ) is the probability of capturing a marked individual in one of three temporary removal passes conditional on it being present in the sampled population at \( t \).

We defined each state as a combination of age class and stream reach (52). The transition probability \( \psi(\kappa) \), therefore, is the probability that an individual in state \( r \) (age \( a_r \), in reach \( r \)) at time \( t \) is found in state \( s \) (age \( a_s \), in reach \( r_s \)) in time \( t + 1 \), conditional on survival from \( t \) to \( t + 1 \) and presence in the study system at \( t + 1 \). We investigated five models (Table 1) representing different constraints on the estimation of transition probabilities, and reflecting our hypotheses that stream salamander movement differed by pathway (overland vs. in-stream) and location in time. Sources of variation in larval movement (no movement, upstream, downstream, or overland) and the type of age transition (remain as larvae, remain juvenile, remain adult, transform from larva to juvenile, or recruit from juvenile to adult).

Our global model included the additive effects of stream reach, age class, and sampling season as sources of variation in survival probabilities ( \( \psi(\kappa) \), the type of movement (no movement, upstream, downstream, or overland) and the type of age transition (remain as larvae, remain juvenile, remain adult, transform from larva to juvenile, or recruit from juvenile to adult).

We expected transition probabilities for July to September were fixed at zero. Because all larvae were observed to metamorphose before July, larval transition probabilities for July to September were fixed at zero.

We used program U-CARE (54) to perform the goodness-of-fit test on the global model. The global multisite test indicated some lack of fit in one of the streams pair, and an investigation of Test3.Sr indicated that the problem was likely caused by transients. Transients were animals that were traveling through the study area (or experienced a handling effect), which led to extremely low probabilities of being present in future occasions. Within each age class, we, therefore, estimated different survival parameters for the time period immediately following initial capture versus subsequent periods.

We used a sequential modeling approach. We first found parsimonious models (using small-sample Akaike’s Information Criterion (AICc) to rank models) for the closed-population capture probabilities and survival probabilities. Next, we used the resulting parameterizations to investigate hypotheses about stream salamander transition probabilities, which were conditional on age transition (Table 1).

We investigated transition probabilities for D. monticola and D. fuscus to be similar, stemming from the similarity in life-history characteristics (55) (e.g., short larval period, close association with the stream channel, and overlapping body sizes within each life stage). To examine the evidence for such similarities in the recapture data, we first modeled the capture histories, including species-specific differences in movement probabilities for each movement pathway (overland, upstream, and downstream). Second, we compared this model against one specifying similar movement behaviors between the species but allowing one species to have higher movement probabilities overall. Third, we formally compared these hypotheses using a likelihood ratio test between a model with species-pathway interaction and a model with an additive effect of species. Finally, we tested whether or not the rates were identical between the two species by specifying a model with no species effect and testing this model against the additive model.

Simulation Model. To investigate the consequences of the observed dispersal probabilities in dendritic metapopulations, we modified the model of ref. 56 to conduct a simulation study in a fractal branching network of 15 habitat patches. We investigated two different annual per-patch extinction probabilities (0.01 and 0.1) and varied the within-stream and overland dispersal probabilities. For our simulation of theoretical 15-patch dendritic networks, each stream was considered to be of equal quality. For each model run, we initialized full occupancy of all patches in the network and fixed the time-specific extinction probability in each patch. We investigated two extinction probabilities (0.1 and 0.01) and four movement probabilities (0.0, 0.1, 0.01, and 0.001). At each time step and after random extinctions of habitat patches throughout the network, we allowed colonization of extinct patches through one of three movement routes: (i) upstream, (ii) downstream (set equal to upstream movement), and (iii) overland colonization from one of the two closest neighboring patches within the same hierarchical level. Mortality of dispersers was not considered explicitly in our simulations. The model was run for a maximum of 10,000 time steps (or until full extinction of the network) for all parameter combinations, and each combination was replicated 100 times. To plot our empirical dispersal probabilities with the simulation results, we condensed our capture histories to two occasions (captured in 2007 or 2008) and sampled season as sources of variation in capture probabilities ( \( p_{ij} \)). Because of low capture probabilities of larval individuals, we borrowed information across age classes by assuming no age specificity within the closed-population removal model. Recapture probabilities for secondary sampling occasions within each primary occasion were constrained to zero to reflect our use of temporary removal passes. All transitions ( \( \psi(\kappa) \) ) that were not structurally possible (e.g., from adult to larvae; overland movement of obligatorily aquatic larvae) were fixed at zero. Because all larvae were observed to metamorphose before July, larval transition probabilities for July to September were fixed at zero.
