Edited by Stephen J. Benkovic, Pennsylvania State University, University Park, PA, and approved July 12, 2011 (received for review March 7, 2011)

The de novo and salvage dTTP pathways are essential for maintaining cellular dTTP pools to ensure the faithful replication of both mitochondrial and nuclear DNA. Disregulation of dTTP pools results in mitochondrial dysfunction and nuclear genome instability due to an increase in uracil misincorporation. In this study, we identified a de novo dTMP synthesis pathway in mammalian mitochondria. Mitochondria purified from wild-type Chinese hamster ovary (CHO) cells and HepG2 cells converted dUMP to dTMP in the presence of NADPH and serine, through the activities of mitochondrial serine hydroxymethyltransferase (SHMT2), thymidylate synthase (TYMS), and a novel human mitochondrial dihydrofolate reductase (DHFR) previously thought to be a pseudogene known as dihydrofolate reductase-like protein 1 (DHFRL1). Human DHFRL1, SHMT2, and TYMS were localized to mitochondrial matrix and inner membrane, confirming the presence of this pathway in mitochondria. Knockdown of DHFRL1 using siRNA eliminated DHFR activity in mitochondria. DHFRL1 expression in CHO glyC, a previously uncharacterized mutant glycine auxotrophic cell line, rescued the glycine auxotrophy. De novo thymidylate synthesis activity was diminished in mitochondria isolated from glyA CHO cells that lack SHMT2 activity, as well as mitochondria isolated from wild-type CHO cells treated with methotrexate, a DHFR inhibitor. De novo thymidylate synthesis in mitochondria prevents uracil accumulation in mitochondrial DNA (mtDNA), as uracil levels in mtDNA isolated from glyA CHO cells was 40% higher than observed in mtDNA isolated from wild-type CHO cells. These data indicate that unlike other nucleotides, de novo dTMP synthesis occurs within mitochondria and is essential for mtDNA integrity.

Fig. 1. De novo and salvage pathway synthesis of dTTP. There are two distinct pathways for dTTP synthesis. In the de novo pathway, SHMT catalyzes the conversion of serine and tetrahydrofolate (THF) to methyleneTHF and glycine. TYMS converts methyleneTHF and dUMP to dihydrofolate (DFH) and dTMP. DHF is converted to THF in a NADPH-dependent reaction catalyzed by DHFR. In the salvage pathway, thymidine is phosphorylated by TK to form dTMP.

In this pathway, 5,10-methyleneTHF, a one-carbon donor, is generated from serine by SHMT and used for the conversion of dUMP to dTMP in a reaction catalyzed by TYMS. The TYMS-catalyzed reaction generates dihydrofolate, which is converted to THF in an NADPH-dependent manner by DHFR. The regenerated THF can then be used for subsequent rounds of thymidylate biosynthesis.

Both de novo and salvage dTMP synthesis have been assumed to occur in the cytoplasm to support both nuclear and mtDNA replication, but recent studies have demonstrated nuclear localization of TK1 (9) and the de novo dTMP biosynthesis pathway during S-phase and as a result of DNA damage (10, 11). The inability of the mitochondrial dTMP salvage pathway to support mtDNA synthesis, and recent studies indicating that de novo dTMP synthesis occurs in the nucleus, raised the possibility for a requirement for de novo thymidylate biosynthesis in mitochondria. De novo thymidylate synthesis has been shown to occur in plant mitochondria through the activities of an SHMT isozyme (mitochondrial serine hydroxymethyltransferase (SHMT2)) and a bifunctional enzyme containing both TYMS and DHFR (12). Interestingly, previous studies have localized TYMS to the mitochondria in mammalian cells (1, 13) and in neurospora crassa (14). In mammalian cells, mitochondria contain SHMT2, which is required for formate and glyoxylate synthesis (15), but the third enzyme in the pathway, DHFR, does not localize to the mitochondria (16).

R egulation of cellular dTTP pools is essential for faithful replication of nuclear and mitochondrial DNA (mtDNA), with both depletion and expansion of the pool affecting DNA integrity and human health (1). Depletion of de novo dTMP synthesis results in deoxyuridine misincorporation into nuclear DNA leading to genome instability (2), whereas depletion of mitochondrial dTTP pools, due to mitochondrial deoxyribonucleoside kinases, deoxyguanosine kinase, or thymidine kinase 2 (TK2) mutations are associated with mtDNA-depletion syndromes and severe mitochondrial dysfunction in humans (3). Elevations in dTTP pools, as observed in mitochondrial neurogastrointestinal encephalomyopathy (4), an autosomal recessive disease resulting from decreased levels of cytoplasmic thymidine phosphorylase, results in mtDNA depletion (5), deletions (6), and site-specific point mutations (6).

There are two distinct pathways for thymidine nucleotide synthesis (Fig. 1). The salvage pathway involves the conversion of thymidine to thymidylate, and occurs in the mitochondria and cytoplasm catalyzed by TK2 and thymidine kinase 1 (TK1), respectively (7). Salvage pathway synthesis of dTTP is not sufficient to sustain mtDNA replication (3) and therefore requires de novo dTMP synthesis, which involves the conversion of dUMP to dTMP, catalyzed by the tetrahydrofolate (THF)-dependent enzymes serine hydroxymethyltransferase (SHMT), thymidylate synthase (TYMS), and dihydrofolate reductase (DHFR) (8).
In this study, a de novo dTMP biosynthesis pathway was identified in mammalian mitochondria that includes a unique mitochondrial isozyme of DHFR called DHFRL1, which was previously thought to be a pseudogene (17). De novo dTMP synthesis is shown to be necessary to prevent uracil accumulation in mtDNA.

Results

Mammalian Mitochondria Contain a De Novo dTMP Synthesis Pathway. Purified intact mitochondria from Chinese hamster ovary (CHO) and HepG2 cells (Table 1 and Fig. S1) were capable of catalyzing the formation of \(^{3}\)H-dTMP from unlabeled dUMP, NADPH, and [2,3-\(^{3}\)H]-L-serine in vitro. This activity is a unique demonstration of folate-dependent de novo dTMP biosynthesis in mammalian mitochondria. Methotrexate inhibited dTMP production in mitochondria isolated from wild-type CHO cells. Mitochondria isolated from glyA CHO cell mutants, which lack SHMT2, exhibited a 94% reduction in dTMP synthesis capacity, indicating the essentiality of SHMT2 within mitochondria for de novo dTMP synthesis. Disruption of mitochondria by sonication-reduced de novo dTMP synthesis activity, indicating that compartmentalization within mitochondria, or the formation of complexes within mitochondria, may be important for de novo dTMP synthesis. Alternatively, the reduced activity may reflect dilution or loss of the endogenous folate cofactor pool following sonication.

Identification of DHFRL1 as an Expressed Gene. To determine if alternative human DHFR transcripts are expressed that encode a mitochondrial leader sequence, \(^{5}'\) rapid amplification of cDNA ends (RACE) was conducted using total mRNA isolated from HepG2 cells. Two prominent bands were observed from the \(^{5}'\) RACE experiment. Upon sequencing the two bands, both DHFR and DHFRL1 were identified (Fig. 2A). DHFRL1 is annotated as a mammalian pseudo gene in Entrez Gene, and expressed sequence tags are present (GenBank accession no. DN994912). The DHFR and DHFRL1 primary sequences are 92% identical (Fig. 2B). An energy minimized three-dimensional model of DHFRL1 was constructed using the crystal structure of human DHFR [Protein Data Bank (PDB) ID code 3GHW] as a template. The model of DHFRL1 structure and DHFR structure are highly similar with an rms value of 0.0034 (Fig. S2).

Mitochondria were isolated from HepG2, wild-type CHO, and glyA CHO cells which lack SHMT2 activity. The capacity to convert dUMP and [2,3-\(^{3}\)H]-L-serine to \(^{3}\)H-dTMP was determined in reactions that contained: (i) sonicated mitochondria, (ii) intact mitochondria for both the HepG2 and CHO cell reactions; and (iii) intact mitochondria with 100 \(\mu\)M methotrexate (MTX), a dihydrofolate reductase inhibitor for CHO cell reactions. The reactions were all normalized to the activity obtained from intact mitochondria isolated from wild-type CHO or HepG2 cells and given an arbitrary value of 1.0. Thymidylate synthesis was inhibited in MTX treated reactions (\(p < 0.001, n = 3\)) and in CHO glyA cells (\(p < 0.001, n = 3\)) compared to the activity obtained in intact mitochondria isolated from wild-type CHO cells. Data were analyzed by two-way ANOVA with Tukey post hoc test for treatment. For HepG2, thymidylate synthesis was inhibited in the sonicated mitochondria (\(p = 0.002, n = 3\), t-test). Variation is expressed as SEM. The purity of the mitochondria isolated from HepG2 and CHO cells was verified by immunoblots using mitochondrial and cytoplasmic markers (Fig. 4 and Fig. S2, respectively).

Localization of DHFRL1 and TYMS to Mitochondria. The subcellular localization of DHFRL1 and TYMS were determined by confocal microscopy following the transfection of pCMV6-AC-DHFRL1-GFP and pCMV6-AC-TYMS-GFP constructs into HeLa cells. The mitochondrial control vector pTagGFP-mito was also transfected to visualize mitochondria, and DRAQ5 nuclear stain was used to visualize nuclei. Colocalization of the mitochondrial control protein, and both TYMS-GFP and DHFRL1-GFP fusion proteins, was observed. TYMS-GFP localized to the cytoplasm, mitochondria, and nuclei (Fig. 3A), whereas DHFRL1-GFP was present exclusively within mitochondria (Fig. 3B). DHFRL1, SHMT2, and TYMS endogenous to HepG2 mitochondria were localized to the mitochondrial matrix and inner membrane in fractionated mitochondria (Fig. 3C), consistent with previous localization studies of SHMT2 (18, 19). Using MITOPRED (20, 21), a bioinformatics program for prediction of mitochondrial proteins, no canonical mitochondrial leader sequence was identified for DHFRL1. The primary sequence of DHFRL1 shown in Fig. 2C was sufficient for mitochondrial import. These data demonstrate that both TYMS and DHFRL1 are present in human mitochondria, and indicate that mitochondria contain a complete pathway to conduct de novo thymidylate biosynthesis.

DHFRL1 is a Functional Enzyme in Mitochondria. The presence of DHFR activity in mitochondria was investigated in human HepG2 cells treated with scrambled control siRNA, and siRNA specific to the DHFRL1 5′ untranslated region and not present in the DHFR transcript. The DHFR activity in extracts from mitochondria isolated from the control siRNA (32.4 ± 4.0 nmol/min/mg protein) and DHFRL1-specific siRNA treatments (0.17 ± 0.008 nmol/min/mg protein) were significantly different with a p value of 0.0002 (\(n = 3\)) where error is expressed as SEM. The mitochondria isolated for these assays exhibited no nuclear or cytosolic contamination as determined by immuno-

GlyA CHO cells lack SHMT2 activity and are auxotrophic for glycine (22, 23). mtDNA isolated from wild-type cells contained 40% less uracil than mtDNA from glyA CHO cells (Table 2). These data confirm the importance of SHMT2 activity within mitochondria for the production of dTMP, and demonstrate the importance of mitochondrial dTMP de novo biosynthesis in protecting mtDNA from uracil misincorporation.

DHFRL1 Expression Rescues the Glycine Auxotrophy in glyC CHO Cells. To verify the function of DHFRL1 in mitochondrial folate metabolism, the ability of DHFRL1 to rescue the glycine auxotrophy caused by disrupted mitochondrial folate-metabolism in a previously uncharacterized CHO cell line, glyC, was determined (Fig. 5). Four stable transfectants were selected for G418 resistance from glyC cells electroporated with either an empty pCMV6-AC-GFP plasmid, or a plasmid containing the DHFRL1 cDNA with a 5′ CMV promoter. Stable transfectants containing the pCMV6-AC-GFP empty vector did not rescue the glycine auxotrophy. However, the glycine auxotrophy was rescued in all selected cell lines transfected with the vector that contained the DHFRL1 cDNA. These results confirm that DHFRL1 localizes to mitochondria and can rescue mitochondrial one-carbon metabolism.

Discussion
This study demonstrates that human mitochondria contain an active de novo thymidylate biosynthesis pathway, composed of SHMT2, TYMS and DHFRL1. This study supports two previous
studies that have observed TYMS protein localized within mammalian mitochondria, although the functional significance of these observations was never established (1, 13). Folate-activated one-carbon units for mammalian mitochondrial thymidylate biosynthesis are derived from serine through the catalytic activity of SHMT2; mitochondria lacking functional SHMT2, isolated from glyA CHO cells, exhibited impaired de novo thymidylate synthesis. The discovery of DHFRL1 as the functional mitochondrial enzyme completes the de novo thymidylate synthesis cycle. Inhibition of DHFRL1 expression by siRNA significantly reduced DHFR activity in mitochondria isolated from HepG2 cells. DHFRL1 was previously thought to be a pseudogene and was mapped to chromosome 3q11.2 (17). The mechanism whereby TYMS and DHFRL1 are localized to mitochondria remains to be established as neither protein contains a canonical mitochondrial leader sequence at its amino terminus.

Disruption of mitochondrial folate metabolism results in a glycine auxotrophy due to loss of SHMT2 function (22). In this study, we show that DHFRL1 complements the previously uncharacterized CHO glycine auxotrophic mutant, glyC. Previous reports have observed that glyC mutants have normal SHMT levels in both the cytosol and mitochondria (15, 24). Because the mitochondrial and cytoplasmic folate pools are not in equilibrium, loss of DHFR activity in mitochondria is expected to result in an accumulation of mitochondrial folate as dihydrofolate, thereby depleting THF pools for the SHMT2-catalyzed conversion of serine to glycine.

De novo thymidylate synthesis appears to be required to maintain mtDNA integrity, as glyA cells were observed to have elevated levels of uracil in DNA. During nuclear DNA replication, tTTP is the only deoxyribonucleotide that is not essential for DNA synthesis as dUTP can be incorporated into DNA when tTTP levels fall (2). Results from these studies indicate that impaired de novo thymidylate synthesis in mitochondria also results in deoxyuridylate incorporation in mtDNA. A recent report observed increases in mtDNA deletions in mice lacking the Ung gene undergoing folate deprivation compared to wild-type controls (25). Other studies support a role for de novo thymidylate biosynthesis in maintaining DNA integrity. Patients with the mitochondrial disorder, Friedrich’s ataxia, which leads to high increases in mtDNA damage, exhibited elevated DHFRL1 mRNA (26). Elevated DHFRL1 expression may help limit some deleterious changes in mtDNA. Other studies have demonstrated that TYMS inhibition leads to caspase-dependent apoptosis and changes in mitochondrial membrane potential (27, 28). mtDNA damage has been shown to initiate apoptosis rapidly, independent of deleterious mutations (29). Mitochondrial DNA damage due to inhibition of mitochondrial dTMP synthesis could explain the increases in apoptosis observed (27). Further investigation should be undertaken to determine if TYMS inhibition-dependent apoptosis is due to uracil misincorporation within mtDNA and/or reduced mitochondrial thymidylate biosynthesis.

Unlike the synthesis of purine and cytosine deoxyribonucleotides, dTMP synthesis is compartmentalized to the nucleus and mitochondria, both sites of DNA replication. Elevated uracil content in DNA results from both nutritional deficiency of folate (2), and from impaired expression of the thymidylate biosynthesis pathway genes (30); genetic disruption of SHMT1 in mice increases uracil levels in nuclear DNA (31). To our knowledge, impairment of de novo thymidylate biosynthesis has not been shown previously to elevate uracil in mtDNA. These data also indicate that a high level of organization within the mitochondria may be required for efficient dTMP biosynthesis, such as the proposed complex in nuclei for dTMP biosynthesis (11, 32, 33). As observed previously in nuclei, disruption of mitochondria by sonication inhibited thymidylate biosynthesis (11). Others have observed that SHMT2 cross-links to mtDNA in HeLa cells upon formaldehyde treatment (34, 35). Collectively, these data suggest that a multienzyme complex may exist within mitochondria at mtDNA replication forks. Ongoing studies will address the biological necessity for thymidylate biosynthesis within both the nuclei and mitochondria, whereas purine biosynthesis occurs in the cytosol (11, 36).

**Methods**

**Cell Lines and Culture.** HeLa and HepG2 cells were acquired from American Type Culture Collection (ATCC). glyA, a CHO cell mutant lacking SHMT2 activity, was obtained from Larry Thompson, Lawrence Livermore Labs, Livermore, CA. glyC, an uncharacterized CHO cell mutant which is auxotrophic for glycine was obtained from Barry Shane, University of California, Berkeley, CA. All cells were cultured at 37°C in a 5% CO₂ atmosphere. HeLa and HepG2 cells were maintained in minimal essential medium (MEM) (HyClone) with 10% fetal bovine serum (HyClone) and penicillin/streptomycin (Gibco). glyA and glyC cells were cultured in defined minimal essential medium which lacks glycine and supplemented with 10% dialyzed and charcoal treated fetal bovine serum (dMEM), penicillin/streptomycin, and 20 mM leucovorin (Sigma). For the complementation assays, positive growth controls included 200 μM glycine.

**5′ Rapid Amplification of cDNA Ends (5′ RACE) Identifies DHFRL1 Transcript.** Polyadenylated mRNA was isolated from HepG2 cells using the Dynabeads mRNA purification kit (Invitrogen) as per manufacturer’s instructions. The isolated mRNA was then used for 5′ RACE using the FirstChoice RNA-Ligase Mediated RACE kit (Ambion, Inc.) as per manufacturer’s instructions. For the outer and inner amplifications the primers used were 5′-TGG AGG TTC CTT GAG TCT CTC GCT G-3′ and 5′-AGG TCG ATT CTT CTC AGG AAT GGA GA-3′, respectively. The primers were made to detect DHFR but also identified DHFRL1. The outer and inner primers are made to nucleotides 229–252 and 176–201 of both DHFR and DHFRL1 coding sequence. The outer primer has a sequence identity of 96% to DHFRL1. The inner primer has 100% sequence identity to DHFRL1. The nested PCR products were run on a 2% agarose gel. Bands were cut from the gel and purified using the QIAquick gel extraction kit (Qiagen). The isolated cDNA was then Topo cloned using the pCR-Blunt II-Topo vector (Invitrogen) as per manufacturer’s instructions. Topo clones were picked and grown overnight at 37°C for DNA isolation. Plasmid DNA was isolated using a Mini-prep kit from Qiagen as per manufacturer’s instructions. The isolated plasmid DNA was sent to sequencing at the Biotech Resource Center at Cornell University. Primers against the 3′ promoter-primer site present in the pCR-Blunt II-Topo vector was used for sequencing.

**Homology Modeling and Alignment of DHFRL1.** The primary protein sequence of DHFRL1 (GenBank accession no. AAH63379.1) was modeled against the structure of human DHFR (PDB ID code 3GHW) using DeepView/Swiss-PDB viewer 3.7. The iterative Magic Fit of all atoms tool was used to generate a structural alignment. The structure model was then energy minimized using GROMOS96 energy minimization tool. PyMOL was used to generate three-dimensional structures and the RMS was determined using the align action within PyMOL. Primary sequence alignments between DHFR (GenBank accession no. AAH71996.1) and DHFRL1 were generated using the ClustalW tool in Lasergene Megalign software.

**Localization of TYMS and DHFRL1 by Confocal Microscopy in HeLa Cells.** TYMS and DHFRL1 cDNAs were fused to the N terminus of GFP within the pCMV6-AC-GFP vector (Origene). A vector expressing a mitochondrial marker, pTagCFP-mito (Evrogen) was used for control transfections to identify mitochondria. Plasmids were transfected into HeLa cells using the Nucleofector II (Lonza), electroporated into CHO cells at the Cornell Microscope and Imaging Facility. Fluorescence microscopy (Zeiss 710 Confocal system) was used to image all experiments. Binding dye, Draq5 (Biostatus Limited) was used to visualize nuclei. Confocal fluorescence microscopy (Zeiss 710 Confocal system) was used to image all cells at the Cornell Microscope and Imaging Facility.

**Rescue of the Glycine Auxotrophy in CHOGlyC Cells.** TYMS and DHFRL1 cDNAs were fused to the N terminus of GFP within the pCMV6-AC-GFP vector (Origene). A vector expressing a mitochondrial marker, pTagCFP-mito (Evrogen) was used for control transfections to identify mitochondria. Plasmids were transfected into HeLa cells using the Nucleofector II and the nucleofection kit R (Lonza) as per manufacturer’s protocol. The DNA binding dye, Draq5 (Biostatus Limited) was used to visualize nuclei. Confocal fluorescence microscopy (Zeiss 710 Confocal system) was used to image all cells at the Cornell Microscope and Imaging Facility.

**Knockdown of DHFRL1 and Dihydrofolate Reductase Activity in Mitochondria.** DHFRL1-specific siRNA and control scrambled siRNA (Qiagen) were transfected into HepG2 cells using Nucleofection (Lonza) as per manufacturer’s instructions. After a 24 h incubation, mitochondria were isolated using...
Mitochondrial Thymidylate Biosynthesis Assay. Mitochondria were isolated from 10^7 cells of each HepG2, wild-type CHO and glyA CHO cells. Cells were grown in Hypflasks (Corning) in DMEM (Gibco) supplemented with 10% fetal bovine serum (HyClone) and penicillin/streptomycin (Gibco). Cells were trypsinized and collected in 50 mL conical tubes and centrifuged at 2,000 rpm for 5 min. The cell pellets were washed twice with phosphate buffered saline with centrifugation at 2,000 rpm between washes. Isolation of mitochondrial fractions were completed as previously reported (38). The mitochondrial pellets were then resuspended in buffer containing 0.3 M sucrose, 1 mM dUMP, and 0.3 M sucrose. The mitochondria used for the sonicated reaction buffer containing 5 mM NADPH (Sigma), 100 mM 2,5 0m MK Cl, 25m KM KPO4, 1 mM dUMP, and 0.3 M sucrose. The mitochondria used for the sonicated reactions were then subjected to five 10 s pulses with 10 s rests between pulses for a total of 10,000. GO IV antibody was used as a mitochondrial control as previously described (11).
