Edited by B. L. Turner, Arizona State University, Tempe, AZ, and approved July 10, 2017 (received for review January 31, 2017)

Wheat, rice, maize, and soybean provide two-thirds of human caloric intake. Assessing the impact of global temperature increase on production of these crops is therefore critical to maintaining global food supply, but different studies have yielded different results. Here, we investigated the impacts of temperature on yields of the four crops by compiling extensive published results from four analytical methods: global grid-based and local point-based models, statistical regressions, and field-warming experiments. Results from the different methods consistently showed negative temperature impacts on crop yield at the global scale, generally underpinned by similar impacts at country and site scales. Without CO2 fertilization, effective adaptation, and genetic improvement, each degree-Celsius increase in global mean temperature would, on average, reduce global yields of wheat by 6.0%, rice by 3.2%, maize by 7.4%, and soybean by 3.1%. Results are highly heterogeneous across crops and geographical areas, with some positive impact estimates. Multimethod analyses improved the confidence in assessments of future climate impacts on global major crops and suggest crop- and region-specific adaptation strategies to ensure food security for an increasing world population.

Significance

Agricultural production is vulnerable to climate change. Understanding climate change, especially the temperature impacts, is critical if policymakers, agriculturalists, and crop breeders are to ensure global food security. Our study, by compiling extensive published results from four analytical methods, shows that independent methods consistently estimated negative temperature impacts on yields of four major crops at the global scale, generally underpinned by similar impacts at country and site scales. Multimethod analyses improved the confidence in assessments of future climate impacts on global major crops, with important implications for developing crop- and region-specific adaptation strategies to ensure future food supply of an increasing world population.

Several methods have been developed to assess the impact of temperature increase on crop yields (6). Process-based crop models characterize crop growth and development in daily time steps and can be used to simulate the temperature response of yield either in areas around the globe defined by grids or at selected field sites or points (1, 7). A third method, statistical modeling, uses observed regional yields and historical weather records to fit regression functions to predict crop responses (8, 9). A fourth method is to artificially warm crops under near-natural field conditions to directly measure the impact of increased

climate change impact | global food security | major food crops | temperature increase | yield

Crops are sensitive to climate change, including changes in temperature and precipitation, and to rising atmospheric CO2 concentration (1, 2). Among the changes, temperature increase has the most likely negative impact on crop yields (3, 4), and regional temperature changes can be projected from climate models with more certainty than precipitation. Meteorological records show that mean annual temperatures over areas where wheat, rice, maize, and soybean are grown have increased by −1 °C during the last century (Fig. 1A) and are expected to continue to increase over the next century (Fig. 1B) —more so if greenhouse gas emissions continue to increase. It is thus necessary to quantify the impact of temperature increase on global crop yields, including any spatial variations, to first assess the risk to world food security, and then to develop targeted adaptive strategies to feed a burgeoning world population (5).

This article was published on August 29, 2017 and is part of the August 29, 2017 issue of PNAS.
temperatures (4). Here, we combine these four methods, which use disparate data sources, time spans, and upsampling approaches (10), to assess the impact of increasing temperatures on yields of wheat, rice, maize, and soybean. Grid- and point-based simulations from recent international model intercomparison exercises (2, 7, 11, 12) and published results of 13 statistical regression studies and 54 field-warming experiments (SI Appendix, Fig. S1) are synthesized (Materials and Methods).

Results and Discussion

Fig. 2A illustrates the impact of temperature on yields of the four crops at the global scale. The loss in yield for each degree Celsius increase in global mean temperature is largest for maize (with multimethod average ± 2 SE) of −7.4 ± 4.5% per degree Celsius. All four methods predict a negative impact for maize, but with varying magnitudes. Mostly the different methods generated similar results at the country scale (Fig. 3C and SI Appendix, Figs. S2 and S3), but estimates varied between countries. The impact estimates are consistently negative for four major maize producers, together responsible for two-thirds of global maize production—namely, the United States (−10.3 ± 5.4% per degree Celsius), China (−8.0 ± 6.1% per degree Celsius), Brazil (−5.5 ± 4.5% per degree Celsius), and India (−5.2 ± 4.5% per degree Celsius). The estimated impact on maize crops in France, however, is smaller (−2.6 ± 6.9% per degree Celsius), including a small positive estimate (3.8 ± 5.2% per degree Celsius) from statistical modeling (13).

For wheat, the average estimate from all four methods is a 6.0 ± 2.9% loss in global yield with each degree-Celsius increase in temperature (Fig. 2A). Results from the four methods agree more closely on the impact on wheat (−7.8 to −4.1% per degree Celsius) than on maize yields (Fig. 2A). The results from different methods are also generally consistent for the top five wheat-producing countries (Fig. 3A) that harvest >50% of the world’s wheat. Spatially, however, the impacts are highly heterogeneous. Estimated wheat yield losses for the United States (−5.5 ± 4.4% per degree Celsius) and France (−6.0 ± 4.2% per degree Celsius) are similar to the global average, while those for India (−9.1 ± 5.4% per degree Celsius) and Russia (−7.8 ± 6.3% per degree Celsius) are more vulnerable to temperature increase. The large yield reductions for Russia are mainly due to the contribution of a markedly higher negative result from the statistical method (−14.7 ± 3.8% per degree Celsius; Fig. 3A), which did not account for in-season variations in temperature impact (10). By contrast, for China, the largest wheat producer in the world, the multimethod estimate indicates that only 2.6 ± 3.1% of yield would be lost for each degree-Celsius increase in global mean temperature.

Rice is a main source of calories in developing countries. The analysis from the multimethod ensemble indicates that a global increase in temperature of 1 °C will reduce global rice yield by an average of 3.2 ± 3.7%, much less than for maize and wheat (Fig. 2A). Grid- and point-based simulations and field-warming experiments indicate a negative impact of temperature of approximately −6.0% per degree Celsius, but some statistical regressions suggest almost no impact. Similar disparities in estimates between the statistical regressions and other methods are found for several major rice-producing countries (Fig. 3B).

Fig. 1. Mean annual temperature changes over time. (A) Historically observed temperature anomalies relative to 1961–1990 for global growing areas of four individual crops. (B) Future projected temperature changes (2071–2100 in comparison with 1981–2010 baseline) of four crop-growing areas and the globe (land and sea surface) under four representative concentration pathway (RCP) scenarios of increasing greenhouse gas concentrations. Error bars represent SDs in the climate model results.

Fig. 2. Multimethod estimates of global crop yield changes in response to temperature increase. (A) Impacts on crop yields of a 1 °C increase in global temperature in grid-based simulations (Grid-Sim), point-based simulations (Point-Sim), field-warming experiments (Point-Obs), and statistical regressions at the country level (Regres_A) (9) and the global level (Regres_B) (8). Circles, means of estimates from each method or medians for Grid- and Point-Sim. Filled bars, means of the multimethod ensemble. Error bars show 95% CIs for individual methods (gray lines) and the ensemble of methods (black lines). (B) Projected changes in yield due to temperature changes by the end of the 21st century. CIs of 95% are given in square brackets.
including China, which produces ~30% of the world’s rice (14). Similar regression methods produce quite different estimates for Indonesia, Bangladesh, and Vietnam, which, when averaged across all methods, lead to small estimated impacts on rice production for each country. For India, however, estimates from all methods predict large temperature impacts, with a multimethod average of $-6.6 \pm 3.8\%$ per degree Celsius.

Soybean is the fourth most important commodity crop (14). Results of just three studies using only two methods are available for global-scale estimates of the impacts of temperature on soybean yield. The global average reduction in soybean yield is 3.1% per degree-Celsius rise (Fig. 24), but the estimates are not statistically significant due to large uncertainties in each method (the 95% CIs go through zero). Similar effects are estimated with both methods for the United States, Brazil, Argentina, and Paraguay (Fig. 3D), which produce 84% of the global soybean harvest (14). The largest expected reduction is $-6.8 \pm 7.1\%$ per degree Celsius for the United States, the largest soybean producer. The overall results for China, the fourth largest producer, however, do not indicate statistically significant effects of temperature on soybean yield.

We compared different methods for a total of 10 sites and found that method estimates are similar for most site-crop combinations.
To prepare for adaptation to climate change, it is necessary to isolate the effects of individual factor for possible impacts on yield, as changes in different factors usually require different adaptation strategies. While elevated atmospheric CO₂ concentration can stimulate growth when nutrients are not limited, it will also increase canopy temperature from more closed stomata (19). Also, changes in precipitation can have an effect on crops, but projections on precipitation change are often uncertain. The focus of our study is on temperature change, one of the most direct negative impacts from climate change on crops, and does not include other possible climate change effects from elevated atmospheric CO₂ concentration or changes in rainfall, and possible deliberate adaptation taken by farmers. Farmers have increased yields through adapting new technologies during the last half-century, but yield has been also lost through increases in temperatures already (9). Yield increase has slowed down or even stagnated during the last years in some parts of the world (20, 21), and further increases in temperature will continue to suppress yields, despite farmers’ adaptation efforts.

The direct negative temperature impact on yield could be additionally affected via indirect temperature impacts. For instance, increasing temperature will increase atmospheric water demand, which could lead to additional water stress from increased water pressure deficits, subsequently reducing soil moisture and decreasing yield (22, 23). However, an accelerated phenology from increased temperatures leads to a shorter growing period and less days of crop water use within a cropping season. Such indirect temperature effects are taken into account in each of the methods, but are not explicitly quantified. Other indirect temperature impacts include more frequent heat waves and possible temperature impacts on weeds, pests, and diseases (18, 24–26). Increases in management intensity and yield potential could also unintentionally increase yield sensitivity to weather (27).

By combining four different methods, our comprehensive assessment of the impacts of increasing temperatures on major global crops shows substantial risks for agricultural production, already stagnating in some parts of the world (20, 21). However, differences in temperature responses of crops around the world suggest that some mitigation could be possible to substantially affect the magnitude (or even direction) of climate change impacts on agriculture. These impacts will also vary substantially for crops and regions, and may interact with changes in precipitation and atmospheric CO₂, so a reinvigoration of national research and extension programs is urgently needed to offset future impacts of climate change, including temperature increase on agriculture by using crop- and region-specific adaptation strategies.

Materials and Methods

Temperature Data. Historical observed gridded monthly temperature data are from the Climate Research Unit (0.5° × 0.5° grid, CRU TS 3.23; https://crudata.uea.ac.uk/cru/data/temperature). Future predicted temperature data are from the Coupled Model Intercomparison Project Phase 5 (CMIP5) Earth System Models (ESMs) outputs (1.0° × 1.0° grids; cmip-pcmdi.llnl.gov/cmip5) used in the Intergovernmental Panel on Climate Change (IPCC) Assessment Report 5 (28). According to data availability, the outputs from 15, 20, 11, and 22 ESMs were included in this study for RCP2.6, RCP4.5, RCP6.0, and RCP8.5 scenarios, respectively. However, the calculated temperature changes are very similar to those calculated by using all of the ESMs (IPCC 5). The annual mean temperature over the global growing area of an individual crop was calculated by weighting each grid cell average (0.5° × 0.5° grids) according to the crop growing area within the grid cell (29).

Global Gridded Crop Model Simulations. The Agricultural Model Intercomparison and Improvement Project (AgMIP) (30) and Inter-Sectoral Impact Model Intercomparison Project (ISIMIP) (31) initiated a fast-track global climate impact assessment for the main global crops in 2012, including wheat, rice, maize, and soybean. Seven global gridded crop models were used to simulate crop yield in 0.5° × 0.5° grid cells over the globe, forced with climate reconstruction for
1900–2009 based on HadGEM2-ES (29) derived from CMIP5. The simulations were carried out under a scenario of constant CO2 concentration (380 ppm in 2000) and full irrigation, to exclude the possibility of covariance with CO2 and precipitation. More detailed information about the simulations can be found in refs. 1 and 33. Temperature impact values were calculated from yield changes between 2029 and 2058 (+2 °C of global mean temperature) and 1981–2010 (baseline), which were then halved to give +1 °C of global temperature impact. For global or country results, all of the grids were averaged by weighting the corresponding growing area of each crop (29).

Point-Based Ensemble Simulations. The AgMIP (30) also conducted crop yield simulations at 30, 4, and 4 representative sites around the world (SI Appendix, Fig. S1) by using 30 wheat, 13 rice, and 19 maize models, respectively. For wheat, a scenario of +2 °C was created by adjusting each day’s temperature by +2 °C relative to the baseline (1981–2010), with other factors being constant. For rice and maize, the +3 °C scenarios were used. Model details about simulations for each crop can be found in refs. 7, 11, and 12. The temperature impact was calculated as the yield change during the warming period relative to the yield during the baseline period normalized to +1 °C impact, assuming the impact showed a linear temperature response. To obtain values for impacts at the country scale, each country was deemed to be similar to one or more representative sites located in the said or nearby country. As local temperature change varied across different climate impacts from diverse production systems and is also one limitation in our analysis. No point-based model-ensemble simulations for soybean were conducted in AgMIP.

Field-Warming Experiments. We started with all published peer-reviewed studies that applied artificial warming treatments on field crops. To avoid introducing warming treatments other than those that are based on climate change, we excluded all-day warming treatments for >2 mo. Results from laboratory incubators or controlled environments with constant day–night temperature treatment (e.g., 37/29 °C vs. 29/21 °C) were excluded. The studies with temperature change (ΔT) unequal to +1 °C were adjusted to +1 °C impact by dividing the impact value by ΔT, which assumed a linear relationship between impacts and ΔT. The studies that produced temperature impacts of >50% per °C were deemed as outliers and excluded. A total of 46 published studies (available from the corresponding author upon request) and 48 sites (SI Appendix, Fig. S1) were therefore included in the following analysis. Most of the sites (41 of 48) had a warming magnitude of 1.5–3.0 °C, similar to the grid- and point-based simulations. The upscaling methods from site to country to global scale are the same as for the point-based model simulations.

Statistical Regressions. Statistical models used regression equations to link historical year-to-year variations in yield to variations in selected climate variables. Different detrending methods were applied in the model to remove the influence of adaptation measures, such as crop management. In the statistical regression studies used here, the global-level results of regressions A and B (Fig. 2A) used detrending methods with the inclusion of a quadratic time trend and first differences, respectively, and resulted in more similar temperature impacts than grid- or point-based simulations. A similar result was found for the country-level regressions A and C (the country-level results are in Fig. 3), which used detrending methods with inclusion of a quadratic time trend and first-differences method, respectively. The results from statistical models were from 13 published studies (available from the corresponding author upon request). The interannual fluctuation in temperature over the globe is ~2 °C (8), similar to the warming magnitude used in other methods. To ensure comparability of results, reported values under local temperature changes were normalized to global surface temperature changes by multiplying the corresponding temperature factor produced by HagGEM2-ES (28).

Multimethod Ensemble. The above four methods constituted the method ensemble that we used to estimate multimethod means and uncertainties. In this study, values from the method ensembles were synthesized at site, country, and global scales. At the country scale, the temperature impacts from regression methods were only reported for the five countries producing each crop; thus, the results mainly focus on the relevant top five countries. The uncertainty for the method ensemble was calculated by using a formula: var(Y) = var(E[method]) + E[var(ΔTmethod)], where the term var(E[method]) is a measure of the variability between methods, and E[var(ΔTmethod)] is a measure of the average variability within methods, assuming that this is random sample of approaches from a population of approaches. Confidence intervals (CIs) at 95% were calculated for the multimethod mean as: 95% CI = mean of methods ± 1.96 × SE(var(Y)).

Comparisons Between Methods. A recent study by Liu et al. (2016) (10) compared the temperature impacts on wheat yield estimated by three different methods. We extended the analyses by including a large number of datasets from site-based observations (field-warming experiments) and comparing estimated impacts on yields of wheat, rice, maize, and soybean—the four most important staple crops for humans. At the country scale, different methods were compared across countries. For the regression method, the results were only reported for the five major countries producing each crop, and thus the comparisons only focused on the relevant five countries. At the site scale, grid-based simulations were compared with site-based simulations and field-warming experiments. Grids containing sites of point-based simulations or warming experiments were selected. The comparisons included absolute yield under different temperature scenarios and relative temperature impacts. The baseline and temperature period for each grid was determined when the rolling 30-y annual mean temperature was equal to the baseline and increased temperatures used for point-based simulations and experiments. The temperature impact was calculated as the yield changes relative to the baseline and then adjusted to a +1 °C global temperature impact.

Prediction of Yield Changes by the End of Century. The yield change by the end of century was calculated as the products of the ensemble estimated yield response and projections of global temperature rise from CMIP5. As the yield response (Fig. 2A) and predicted temperature change (Fig. 1B) both have uncertainties, a bootstrap resampling approach was used to obtain the predicted yield change and its uncertainty. At each instance of bootstrap resampling, one pair of values for yield response and temperature change was sampled, respectively, from their original data to calculate the predicted yield change; this procedure assumes the chosen value is a random sample from a population of values. Repeating the above process 5,000 times gave 5,000 values of predicted yield change, which constitute a new distribution of the predicted yield change. The 2.5th–97.5th percentile was deemed as the boundaries of uncertainty for the predicted yield change.

Figs. S1 to S4
Figure S1. Maps of study sites for point-based model-ensemble simulations and field warming experiments that focused on the warming impacts on yields of four crops. For simulation experiments, only multi-model results were used (i.e. no single model applications were included here). Crop-growing area data from Monfreda et al. 2008 (29) is shown by green shading. For model-ensemble simulations, there are in total 30 sites for wheat, 4 for rice, and 4 for maize. For field warming experiments, there are in total 25 experimental sites for wheat, 15 for rice, 5 for maize and 3 for soybean.
Figure S2. Country-scale pairwise comparisons of Grid-Sim, Point-Sim and Point-Obs method estimates of +1 °C global temperature impact on crop yield. The size of the circles is proportional to the country’s annual crop productions (FAO, 2014). The color of circles represents the baseline (1981-2010) mean annual temperature (MAT) for each country’s crop growing area (AgCFSR; http://data.giss.nasa.gov/impacts/agmipcf/). The weighted linear regressions were used to explore the relationship between different methods with weighting factors for each country’s production. For maize, the observed data from China (outlier) was not included in the regression.
Figure S3. Comparison of estimates of +1 °C global temperature impacts on yields from Grid-Sim, Point-Sim and Point-Obs with Regres_A methods for the five major countries producing each crop (10). The size of circles represents the country’s annual crop production (15). The color of circles represents the baseline (1981-2010) mean annual temperature (MAT) for each country’s crop growing area (AgCFSR; http://data.giss.nasa.gov/impacts/agmipcf/).
Figure S4. Site-scale estimates of +1 °C global temperature impact from Grid-Sim compared with Point-Sim and Point-Obs methods. The comparisons include absolute yield impacts for periods of baseline (1981-2010) and baseline+1 °C global temperature and relative yield change. Note, more relative impact observations were available than absolute impact. The color of symbols represents baseline mean annual temperature (MAT; AgCFSR; http://data.giss.nasa.gov/impacts/agmipcf/). Triangles and circles represent point-based model-ensemble simulation and field warming experiment, respectively. Linear regressions were used to explore the relationship between point-based and grid-based methods. For maize, the observed data from China (outlier) was not included in the regression.
