Glaciers cover ~10% of the Earth’s land surface, but they are shrinking rapidly across most parts of the world, leading to cascading impacts on downstream systems. Glaciers impart unique footprints on river flow at times when other water sources are low. Changes in river hydrology and morphology caused by climate-induced glacier loss are projected to be the greatest of any hydrological system, with major implications for riverine and near-shore marine environments. Here, we synthesize current evidence of how glacier shrinkage will alter hydrological regimes, sediment transport, and biogeochemical and contaminant fluxes from rivers to oceans. This will profoundly influence the natural environment, including many facets of biodiversity, and the ecosystem services that glacier-fed rivers provide to humans, particularly provision of water for agriculture, hydropower, and consumption. We conclude that human society must plan adaptation and mitigation measures for the full breadth of impacts in all affected regions caused by glacier shrinkage.

Glacier | runoff | biogeochemistry | biodiversity | ecosystem services

Global-scale understanding of glacier mass loss has improved significantly in the past decade, principally via advances in satellite remote-sensing instrumentation and processing. Previous estimates of mass loss were extrapolated from sparsely distributed in situ observations (1), whereas field measurements are now combined routinely with globally complete glacier inventories (2) and direct measurements of volume and mass change from satellite altimetry and gravimetry to provide accurate estimates of global glacier mass change (3). The most recent estimate of global glacier change indicates a mass loss rate of 259 ± 28 Gt y−1 between 2003 and 2009 (3), with global runoff from glaciers exceeding 1,350 km3 y−1 (4). Research to date on the associated downstream impacts of this glacier mass loss has focused largely on sea-level rise (3, 5) and to a lesser extent, on water availability and runoff (6). The scale of ice loss worldwide creates an urgent need to evaluate comprehensively the broader spectrum of downstream effects on freshwater and near-shore marine systems. This increased understanding is vital to aid planning for adaptation and mitigation measures in the most significantly affected regions. The largest individual contributions to global glacier mass loss come from the glaciers of the Gulf of Alaska, the Canadian Arctic, and the ice sheet peripheries of Greenland and Antarctica. However, the glaciers with the most negative mass balances are located in the European Alps and at low latitudes in the South American Andes (3). In the European Alps, atmospheric warming has been pronounced in the last 30 years, especially during the summer months, which when combined with decreased snowfall, has led...
to a 54% loss of ice area since 1850; current projections suggest that just 4–13% of the 2003 European Alps ice area will remain by 2100 (7, 8). Similarly, in South America, Bolivian glaciers have lost nearly 50% of their mass in the last 50 years (9), and in western Canada, glacier ice volume relative to 2005 is projected to decrease 70 ± 10% by 2100 (10). Glaciers in the Ganges, Indus, and Brahmaputra Rivers basins of the Himalaya are currently losing 24 ± 2 Gt y⁻¹ of ice (11), equivalent to around 10% of the global glacier mass loss between 2003 and 2009 (3). Climate-driven changes in glacier volume will alter the timing, magnitude, and frequency of downstream discharge, sediment transport, and the speciation of nutrients, with far-reaching consequences for downstream ecosystems, including rivers, lakes, and the coastal zones of major oceans, and the human populations that depend on them (12).

The downstream impacts along the continuum from glaciers to rivers to the ocean affect various ecosystem levels ranging from shifts in biogeochemical and sediment fluxes (13, 14) to loss of biodiversity (15, 16) and perturbed food web dynamics (17). Glacier shrinkage also will have important implications for the ecosystem services that glacier-fed rivers provide, particularly in regions where glacier runoff is integral to multiple human activities, such as farming, energy production, water supply/quality, and tourism. The scale of potential changes faced by society is immense. For example, Himalayan glaciers alone provide water to 1.4 billion people (18). Here, we examine multiple lines of evidence from glacier-fed systems globally to develop a framework to synthesize existing information and expert understanding about how glacier shrinkage and changes in runoff regimes will impact downstream ecosystems and human society. We have developed integrated conceptual models of how discharge, nutrients, ecological communities, and ecosystem services respond as glacial cover decreases over time with ongoing climate warming (Fig. 1). Building on this framework, we present a globally integrated perspective into the complex adaptation decisions required with respect to changing ecosystem services and associated societal adaptations within glacierized regions.

**Hydro- and Geomorphological Implications of Glacier Melt**

Estimating the quantity and timing of melt water runoff in relation to glacier mass balance is a major challenge because of complex hydroclimatological interactions across different spatial scales and climatic zones (6). A significant amount of “glacial” runoff is sourced from the melt of annual snowfall that passes over or on the surface of the glacial ice, which will still occur in the absence of a glacier. However, snowmelt-dominated systems have a more variable and temporally constrained hydrological regime compared with glacially-dominated systems. Glacier runoff continues as long as there is energy for melt because of the ice reservoir. Hence, the loss or substantial reduction of ice will lead to distinct changes in the timing and magnitude of runoff peaks (19). Glacial ice melt runoff typically peaks during summer in mid- to high-latitude regions, when runoff from other sources is typically low, thereby buffering dry season stream discharge from precipitation and snowmelt variability (Fig. 2A, high glacier cover) (20) and preventing drought in some regions (12). Over longer timescales, regions with extensive glacier cover, such as the northeastern Canadian Arctic and Svalbard, are predicted to see an initial increase in annual glacier runoff (4) because of the earlier disappearance of the reflective snow cover and the exposure of ice with lower surface albedo. However, this initial bulk discharge increase (Fig. 1A) will be followed by reduced annual runoff caused by the ensuing decrease in glacier volume (21), such as is presently observed with smaller glaciers. Paired long-term glacier mass balance and streamflow records in Alaska suggest that the overall loss of glaciers will decrease total catchment runoff by 10–20% (22). During the coming century, as total runoff from glaciers decreases in most regions (Fig. 1A), river flow in summer will become more sensitive to precipitation events, particularly if these become more extreme with climate change.

On annual timescales, glacier runoff produces a deterministic, predictable hydrograph in temperate and Arctic glacier-fed rivers. Future decreases in glacier runoff will result in a shift toward a more stochastic hydrological regime in these watersheds (Fig. 2A). In particular, the replacement of predictable summer glacier melt by less predictable rainfall events and snowmelt runoff regimes will increase the relative magnitude and seasonal duration of short-term flow variability (Fig. 2B). These shifts are already evident for glacierized
catchments in the Pyrenees and Alps, showing that, in watersheds with low glacial influence, river flows in spring and fall will be higher with more variability (Fig. 2D) than when glacier cover is intermediate or high (Fig. 2C). This is caused by a combination of the earlier onset of snow melt and an increased fraction of winter precipitation falling as rain with climate warming (Fig. 2A) (23). Clearly, glacier-driven changes in hydrology will have major implications for downstream ecosystem processes and ecological communities given the known importance of predictable annual flow pulses for river biodiversity (24). However, this can vary according to region; for example, in the Himalaya, precipitation from the monsoon system provides a deterministic element to the annual flow cycle, although the year-to-year variability will increase without the buffering capacity of glacial runoff (25). Equatorial systems typically have no seasonality but high diurnal variability (26). These systems are ablation-driven with no snow accumulation; therefore, the quantity of meltwater will decrease over time, and the magnitude of this diurnal variability will gradually decrease.

In Nepal and Greenland, basins have formed between the glacier and the lateral or end moraines with rapid ice recession in recent times. Stagnant ice in these basins may melt to form glacial lakes, which can grow rapidly in size (27) and catastrophically discharge as a glacial lake outburst floods. Such geohazards are predicted to increase with ongoing glacier recession in heavily glacierized regions (28) (Fig. 1A), leading to significant societal impacts via loss of life and damage to land, property, and infrastructure (29).

In the long term, reduced glacial runoff will increase summer water temperature downstream because of (i) an increase in atmospheric energy receipt with warmer air temperature (although radiation could be reduced by increased cloudiness), (ii) a decline in the relative contribution of cold water from glacial melt, and (iii) the reduced heat capacity of rivers with lower flow (30). Concomitantly, bedload and suspended sediment load are expected to decrease in the long term as glacial runoff becomes reduced and erosion decreases (31) (Fig. 1A). The resultant decrease in turbidity will increase light penetration to the bed of streams and rivers, with implications for primary production and the photochemical transformation of organic matter enhanced by increased channel stability where braiding of river channels is less (31).

Glacier retreat is likely to expose new areas of unconsolidated glacial sediments and to destabilize slopes in many areas (32), creating the potential for hazardous landslides (Fig. 1A) and short-term increases in sediment yields from glacial basins. On steeper slopes, where vegetation cannot be established, sediment yields will occur for a longer time period (33). An additional consequence of a reduction in glacier volume in polar areas may be a decrease in sediment yield from glaciers undergoing changes in their thermal regime (34). Ice overburden pressure and heat release by deformation and strain heating will be reduced by glacier thinning, potentially reducing the energy available for subglacial erosion, especially in cases where the energy loss causes a reduction in basal sliding. Ultimately, thinning glaciers may even freeze onto the bed. However, this decrease in sediment yield may be compensated for by mobilization of paraglacial sedimentary materials from thermoerosion of ice-cored moraines and increased prevalence of ice-marginal landslides and debris flows (35). The net result is a shift from glacial- to paraglacial-dominated mountain catchments, which in the short term (coming decades), will increase sediment supply and associated geohazards within mountain ranges (Fig. 1A).

Biogeochemical Fluxes and Cycling

Recent discoveries highlight glacier perturbations of global and regional biogeochemical cycles (14, 36). Glaciers receive and accumulate dissolved organic carbon (DOC) and inorganic nutrients from both wet and dry deposition. Red-colored green algae growing on the glacier surface can reduce the albedo, thereby increasing melting—a phenomenon known as the “bioalbedo” effect (37). These species are frequently derived from remote sources (38, 39). A wide variety of microorganisms (including algae) assimilate inorganic nutrients within the snow and ice and in meltwater flowing down crevasses and entering sedimentary habitats at the glacier bed (40). Microorganisms transform labile inorganic nutrients, such as ammonium and phosphate, into organic forms (41) that ultimately contribute to the pool of ice-locked organic matter. At a global scale, ice-locked organic matter is substantial and represents a hitherto poorly understood reservoir of carbon (36). The biogeochemical diversity of this organic matter is also unexpectedly high, with many constituents containing proteinaceous molecules, lignins, and tannins (39).

Supraglacial microbial communities are important drivers of the production and export of DOC from glacial ecosystems (42, 43). Studies on Alaskan (38) and alpine (39) glaciers have shown that ice-locked DOC is highly bioavailable (up to 80%) to microbial heterotrophs and that, on release, this DOC can stimulate riverine carbon cycling (39) and sustain aquatic food webs (44) in glacier-fed rivers. Bioreactive proteinaceous molecules have a near-global distribution within glacial meltwaters (45), and changes to the export of this labile substrate to downstream ecosystems will occur with glacial recession. DOC, dissolved inorganic nitrogen (DIN), and dissolved organic nitrogen (DON) concentrations in runoff increase as glacier coverage in the catchment decreases (Fig. 1B and Fig. S1 A–C), although overall DOC bioavailability decreases (Fig. 1B) (38). Although DOC concentrations in glacier runoff are low, fluxes of labile DOC to downstream ecosystems can be substantial because of the relatively high specific discharge in glaciated
watersheds. Glacier runoff may also act as a source of N. For example, a significant flux of reactive N, equivalent to the sum of the dissolved nitrogen, may be associated with NH₄⁺ adsorption onto suspended sediments (14). Glacial sediments also seem to promote nitrification, thereby making glacier basins net exporters of nitrate to downstream ecosystems (46).

The concentration of soluble reactive phosphorus (SRP) is predicted to decrease with declining glacier coverage in the watershed (Fig. 1B and Fig. S1D) (47), and a large proportion of that reactive P flux can also be bound loosely to suspended sediment (14). However, with increasing glacier retreat, DOC, DIN, and DON concentrations are likely to increase, while SRP concentrations will decrease (Fig. 1B). In the short term, dependent on factors such as the flux of glacier meltwater and the concentration of glacial suspended sediment, elevated fluxes of potentially bioavailable NH₄⁺ and P may mitigate declines in dissolved N and P.

An unexpected impact of glacier shrinkage is the liberation of contaminants including emission products from industrial activity (48), such as black carbon and associated compounds, mercury, pesticides, and other persistent organic pollutants (49). Uncertainty exists in how climate change is releasing these contaminants from glacier ice, leading to their transport to downstream systems by meltwater, which should reduce in concentration as glacial ice shrinks (Fig. 1B) (50). Importantly, glaciers now represent the most unstable stores of the so-called legacy pollutants, such as dichlorodiphenyltrichloroethane, in European and other mountain areas flanking large urban centers. Their accumulation in lake ecosystems downstream from glacierized mountains has been modeled using climate-driven mass balance change to alpine glaciers in Europe (48). However, their impacts as they cascade through downstream ecosystems remain largely unexplored, suggesting that the additional study of contaminant dynamics should be extended to a wide range of mountain environments, such as the Himalaya, where meltwater supplies drinking and irrigation water to billions of people.

**Biodiversity**

Diverse ecological communities have adapted over evolutionary timescales to the harsh environmental conditions in glacier-fed streams and rivers. Benthic invertebrate communities play important roles in the flux of biomass and nutrients (C, N, and P) from lower (algal, microbial, detrital resources) to upper trophic levels (fish, birds, mammals, amphibians). Shifts in the hydrological regime will alter the physical and chemical template to which these communities have adapted, ultimately leading to overall loss of biodiversity, ranging from algae to fish (51). The scale of these effects on biodiversity remains poorly quantified (16), with studies to date focusing primarily on community-level changes. Here, we focus on differences among biological groups regarding their ability to withstand changing conditions and the role of phenotypic plasticity and genetic adaptations in response to climatic change.

**Microbial and Algal Communities.** Microbial life in glacier-fed streams is dominated by biofilms that extensively colonize the sediment surface (52). Encapsulated in a polymeric matrix, species from all three domains of life (Archaea, Bacteria, and Eukarya) coexist in these biofilms, where they are protected against harsh environmental conditions, including pronounced variability in flow, high UV radiation, and low availability of organic carbon (52). Benthic biofilms in mid- to high-latitude glacier-fed streams can flourish during optimal environmental windows in spring, when channels unfreeze, flow is low, and the water is clear, and in fall, when similar conditions exist (53). Similarly, benthic biofilms can develop markedly where channels remain open during winter because of upwelling groundwater (54).

Biofilms drive most of the aquatic ecosystem respiration (ER) and gross primary production (GPP) and are, therefore, critical to the carbon and nutrient cycles in glacier-fed rivers. The extension of the temporal period of clear water may cause sites of increased primary production (55) dominated by diatoms and the gold filamentous alga (Hydrurus foetidus) (56). Channels become more stable as glacial inputs diminish, analogous to nonglacial Arctic rivers (57), and bryophytes may become more abundant and compete with benthic algae. Overall, these changes would increase the annual GPP, likely followed by higher ER in these streams as glacial influence becomes markedly reduced (Fig. 1C).

Molecular analyses have recently highlighted surprisingly high bacterial richness in biofilms in glacier-fed rivers (58) caused by turnover between putatively active and dormant taxa continuously recruited from upstream sources in the catchment (e.g., from soils, rocks, groundwater), which maintains high bacterial richness (59). This is advantageous for biofilms to react rapidly to an environment that is continuously subject to physical disturbance and environmental fluctuations. Previous studies suggest that community assembly of microbial biofilms is largely deterministic, involving a series of environmental filters (58, 60). However, with ongoing glacier shrinkage, increasingly unpredictable flows during the spring window when glacier cover is low (Fig. 1A) will likely reduce the optimal period for biofilm growth in glacier-fed rivers. In addition, as glacial runoff further decreases, bacterial communities in biofilms will become more similar to those in rivers fed predominantly by groundwater, snowmelt, and rain, thereby leading to a homogenization of microbial diversity at the landscape level (i.e., loss of β diversity) and decreasing regional diversity (γ diversity) (Fig. 1C) (58, 61).

**Macroinvertebrates.** This group has been well-studied in freshwaters globally and therefore, is typically considered a “model” group for tracking environmental change. Glacially-dominated rivers are characterized typically by the deterministic nature of their benthic macroinvertebrate communities caused by the overriding conditions of low water temperature and low channel stability (62, 63). Substantial changes in macroinvertebrate local diversity (α diversity) and distribution patterns are likely as glacial cover and meltwater runoff decline in catchments and the hydrological regime in glacier-fed rivers become more stochastic (15, 24, 64) (Fig. 1C). Threshold analyses from glacialized river systems in three regions suggests cold stenothermic organisms become extinct when glacial cover falls below 19% for the sub-Arctic, 20.4% for temperate, and 31.8% for equatorial (SI Thresholds and Tipping Points; see Fig. S2 and Table S1). In general, α diversity is expected to increase at the reach level as environmental conditions ameliorate with lower summer discharge and turbidity and higher channel stability and water temperature, with communities tracking optimal water temperature by migrating upstream (65).

A longitudinal displacement of species composition with changes in runoff is intriguing, because during the initial phase of loss of larger glacial masses, increased glacial runoff may cause stream communities to migrate downstream, thereby reducing α diversity (65). However, although in the longer term, α diversity will increase, β and γ diversity are expected to decrease at the stream and catchment level (15, 24, 64, 66) (Fig. 1C), and genetic diversity is expected to decrease at the regional level (66). River reaches will become gradually more homogenous, and unique glacial river specialist species will become extinct because of increase in water
temperature and competition for food and space with newly colonizing species and predator range shifts (67, 68). This is similar to the response for biofilm microbial communities described above. Nevertheless, even as riverine conditions become more favorable to colonization by new, often more ubiquitous species, other factors may restrict establishment (for example, weak dispersal ability, mountain barriers, lack of suitable microhabitats, scarcity of food, or other possible environmental conditions) (51, 69).

Rivers with high glacial influence typically support communities with low taxonomic diversity dominated by highly adapted taxa, which display a convergence of functional traits. Analysis of a unique 27-year record of community assembly after a reduction in glacier cover in southeast Alaska showed that niche-filtering processes were dominant with high glacier cover (63). However, significant shifts in the trait composition of stream invertebrate communities occur as catchment glacial cover decreases (63, 70), with stochastic and deterministic assembly processes co-occurring. Specialist taxa are replaced by more generalist taxa with a greater diversity and width of biological traits (SI Thresholds and Tipping Points).

The size spectra of aquatic biota typically increase with warmer thermal regimes and higher productivity. Thus, as glaciers retreat, larger-sized predators (e.g., fish, amphibians, mammals, large invertebrates) will colonize rivers or move upstream in greater abundance (Fig. 1C) (65). Functional diversity and functional redundancy increase rapidly (63, 70), as new colonizers possess many similar traits to taxa already present, thereby contributing to the functional resilience to additional ecosystem change.

The adaptive potential (evolutionary and phenotypic) of aquatic biota to projected changes in glacial runoff is not well-known (71), but dispersion and phenotypical plasticity provide a possibility for some threatened taxa to respond to climate and environmental changes in the short term (72). Dispersal propensity and the level of specialization and capacity to exploit refugia are important considerations. Traits, such as semivoltinism, light bodies and good adult fliers, eurythermy, and generalist feeding, typically associated with high dispersal capacity might allow threatened invertebrates to survive environmental changes. Some species may avoid extinction as glacial relics in groundwater systems as shown by the cold stenothermal stygobiotic crustacean Niphargus strouhalii alpinus found trapped for at least 150 years in 30-cm sediments in the Italian Alps (73).

### Salmonids

Both Atlantic and Pacific species of salmon and trout provide important sources of proteins to millions of people worldwide and sustain major commercial and sport fisheries. Rising water temperature has been linked to increased mortality of juvenile Chinook salmon, raising concerns over the future viability of this important species (74). Population models indicate a 17% chance of catastrophic loss in the Chinook salmon population by 2100 (74). However, where glacier cover is both intermediate and high, increased glacial melt with climate change will have a cooling effect on monthly mean stream temperature during the summer. For each 10% increase in glacier cover in a catchment, mean stream summer temperature can decrease by >1 °C (75), potentially reducing fish growth. Conversely, future reductions in glacier runoff may actually improve the thermal suitability of glacially-dominated rivers for salmon. An extensive amount of salmon habitat has been created because of glacial recession in Alaska, with >500 systems documented along the southeast coast (76). More work is needed to understand the implications of interacting phenomena, as more extreme weather events, like floods, can conversely significantly reduce salmonid population sizes (77).

Glacier-fed rivers conserve a greater proportion of their annual flow budget for late summer and through winter than streams and rivers fed by snowmelt (78). Increased summer flows in glacier-fed rivers facilitate the migration of anadromous salmon through river corridors to spawning grounds at a time when other sources to flow are typically low (78). Some of the largest runs of anadromous salmon in southcentral Alaska that support commercial and sport fishing occur in glacially influenced rivers (79), but glacier shrinkage will diminish summer discharge, thereby potentially restricting adult salmon spawners migrating upstream. In addition, a more stochastic flow regime in summer (Fig. 1A) will have a negative effect on stream juvenile-rearing salmonids and other fish species. Sockeye salmon have also been shown to prefer the turbid glacial meltwaters for spawning (80), and turbidity can provide cover for rearing fish from predators (81). However, potentially higher flows in winter and early spring may be of benefit to reduce mortality, particularly for overwintering salmonids, a time period when mortality is typically at its highest. Climatic change will likely have widely divergent impacts on the timing of salmon migration, but watershed glacier cover does not influence long-term shifts in the phenology of migration timing (82).

### Food web complexity and ecosystem functioning

The consequences of species extinction on trophic interactions and related matter fluxes in glacier-fed rivers after glacier shrinkage currently remain elusive (51). We know that food webs in glacier-fed rivers can be partly sustained by ancient DOC released from glaciers, which can be transferred to higher trophic levels, including invertebrates and fish after incorporation into bacterial biomass in biofilms (44). The decrease over the long term of a glacial source of organic carbon with ongoing glacier shrinkage will likely be replaced by instream and terrestrial primary production. Species turnover in glacier-fed rivers is linked strongly to glacier shrinkage, where colonizing species likely compete for resources with native species. These changes can be “bottom up” (e.g., from biofilm) (83) or “top down” (e.g., colonization by larger predatory invertebrates) (Fig. 1C) (68). Both mechanisms will potentially influence food web structure and trophic interactions as glaciers vanish (84). This is supported by a four-year experimental flow manipulation in the Ecuadorian Andes, where meltwater reduction led to increased biomass of benthic algal and invertebrate herbivores and furthermore, altered invertebrate community composition within a few weeks (55).

### Ecosystem Services

The seasonal predictability of glacial melt facilitates a range of important socioeconomic ecosystem services, spanning provisioning, regulating, and cultural services (Fig. 3). Provisioning ecosystem services associated with glacier and snowpack storage of water is perhaps the most prominent of the three ecosystem services. The seasonally predictable flow regimes of glacier-fed rivers enable navigation on larger rivers; provide water for hydropower, human consumption, and irrigation for agriculture; and in some regions, support significant freshwater and inshore fisheries. This is particularly important in semiarid and arid regions, where other water source contributions are limited (12, 85). These ecosystem services will be perturbed markedly by the expected shifts of the hydrological regime owing to glacier shrinkage, causing significant economic ramifications.

### Irrigation and Water Supply

In Wyoming, crop production to support a United States dollar (USD) $800 million cattle industry is dependent on glacial meltwater to supply a stable source of water during the growing season. However, from 1985 to 2005, glacier surface area decreased on average by 32%, resulting in 10% less stream flow during this period (86). Agriculture in Alberta is also
dependent on meltwater from the Peyto Glacier and proximal glaciers in the Canadian Rockies, which are estimated to lose 90% of their present volume by 2100 (87). As an example of potential future changes in some regions of the world, the Tien Shan region of China is relatively arid but was once known as the “Green Labyrinth” because of glacial runoff being a significant source of water for agriculture. However, a 20% reduction in volume of 446 glaciers within the region over the period 1964–2004 is already impacting the sustainability of the region’s water sources (88).

In the Andean region of South America, many large populations depend heavily on glacial sources during this season, not only for agriculture but also, for drinking water. For example, 27% of La Paz’s water consumption during the dry season is glacial meltwater from the Cordillera Real (89), which is projected to decrease annually by 12% (90). During the dry season, 40% of the discharge of the Rio Santa, which drains the Cordillera Blanca in Peru, is from glacial runoff (91), providing extensive irrigated areas along the dry Atacama coast as well as 5% of Peru’s electricity (89). Estimated glacial retreat within the upper Rio Santa could lead to a decrease in the dry season average flow by 30% (92), further impacting the provisioning of water, with significant implications for associated provision of agricultural crops.

**Hydropower.** In countries where this is the main source of electricity, glacial runoff contributes significantly to its generation (Iceland: 91% and Norway: 15–20%) (93). Austria generates 70% of its electricity from hydropower, with many large facilities being glacier-fed, while the glacier-fed Rhone River has 19 hydropower plants, supplying 25% of France’s hydropower. In Switzerland, 25% of its electricity is sourced from glacial runoff. The effects of glacier retreat on hydropower revenue are uncertain as a consequence both of predictions in meltwater runoff in future as well as market fluctuations (94). For glacier-fed rivers, ecosystem service valuations are best developed for this sector. For example, the Mauvoisin power plant in Switzerland gathers runoff from nine glaciers, and revenue is expected to increase initially from between USD $87.5–104.3 million (1981–2010) to between USD $87.5–108.6 million in 2021–2050 as a result of increasing rates of glacier retreat and thus, extra runoff generation potential. However, revenue is estimated to fall to USD $74.0–91.3 million by 2071–2100 as glacier runoff declines (94). Estimates of revenue shifts are needed from other regions to develop a more coherent picture of the economic issues associated with glacier retreat.

Current reservoir capacities may be unable to store the additional water from increasing summer melt from larger alpine glaciers, leading to only marginal electricity generation gains but increased numbers of overspill events and associated hazards (95). On the other hand, in the short term, hydropower may benefit from higher hydrological yields in summer (96) but not in the long term as glaciers shrink further or disappear (Fig. 1D). Glacier shrinkage also may open up new terrain for the construction of new dams and reservoirs in valleys not previously suitable for hydropower and now fed from other water sources (96). Shifting of the timing of peak melt compared with peak electricity demand may require society to invest more in storage reservoirs. Although typically holding less ice, rock glaciers may prove to be an important alternative source of water (97). Research into the importance rock glaciers as water sources is relatively new, and a wider inventory and understanding are critical to ensure their future protection.

**Fisheries and Water Quality.** River fisheries provide important sources of food in many regions, and the potential for significant local–regional scale economic perturbations is high if glacier-fed river fisheries change with reductions in glacial melt (Fig. 1D). For example, in the glacial Kenai River in Alaska, sport and commercial fisheries generate as much as USD $70 million to the state’s economy, but increased flow variability and flooding caused by enhanced glacier melting and glacial outburst floods can significantly affect these important fisheries (78). Associated large-scale changes in basin geometry and rerouting of meltwater may significantly affect salmonid habitat (98). However, the creation of new salmon habitat as documented along the Pacific Northwest coast of North America (76) can potentially benefit fisheries.

Glaciers and their downstream river systems provide important regulating services, most notably related to water quality, hazard generation/mitigation, and climate feedbacks via C cycling. Glacial meltwater can dilute pollutants and mitigate water quality modifications associated with river regulation (24). Glaciers can also regulate the influence of harmful contaminant release from the snowpack through storage, which prolongs the opportunities for volatilization and other transformations (99). However, the liberation of historically deposited pollutants could significantly reduce water quality downstream. Reduced suspended sediment load caused by glacier retreat can lead to decreases in erosional processes. Glacier shrinkage is, furthermore, creating thousands of new lakes worldwide, where outburst floods are increasingly threatening hydropower facilities and downstream settlements (28, 29). There are only a handful of detailed studies available at present to underpin our understanding of current and future regulating services of glacier-fed rivers and a pressing need for detailed studies integrating a range of scenarios.

**Cultural Services.** Among those provided by glacialized mountain landscapes, tourism makes a particularly important contribution to the economy of many regions. For example, the glaciers of Banff National...
create new highland reservoirs to supply water during the dry season, leading to knock on changes among regulating services currently provided by downstream river systems. This could necessitate a shift from hydropower electricity generation to other sources (90) to retain water for food. Other solutions could be behavioral (for example, reductions in water use and waste) and managerial in terms of water source management (9). The development of new storage facilities would, in turn, lead to alteration to landscape character, which for some groups, may be seen as a negative for cultural tourism-related services. In 2010, Argentina became the first country to adopt a multifaceted Glacier Protection Act that aims to preserve glaciers as “strategic reserves of water for human consumption, for agriculture and as suppliers of water to recharge basins, for the protection of biodiversity; and as a source of scientific and tourist attraction” (110). This kind of solution may become more common to prevent modifications within glacierized watersheds but is unlikely to be useful in the face of global climate change unless adopted internationally as an additional driver of emissions mitigation policies.

Summary

The area of land occupied by glaciers will decrease significantly by the end of the present century. Although the impact of melting glaciers on sea levels has received much attention to date, our synthesis clearly outlines other multiple downstream effects that will alter riverine ecosystems with significant societal implications. There will be major changes to flow regimes in glacierized watersheds, with a shift to greater stochasticity as glacial runoff decreases and flow becomes more dependent on unpredictable precipitation events and snow melt. Among the major impacts, there are profound changes to ecosystem functions and services via altered provision of water resources to human society, reorganization of the regulatory processes that shape water quality and geohazards, and cultural changes associated with tourism, landscape character, and religion. Clearly, the breadth and complexity of interactions among the various impacts will underpin calls for a global research agenda involving interdisciplinary research to meet the following research priorities, which need urgent attention to inform effective societal adaptation.

i) High-resolution (space and time) mapping of glacier mass loss based on new imagery and technologies.

ii) Global census and continuous monitoring of key biogeochemical variables, contaminants, and biodiversity in glacier-fed rivers using a network of sites with a wide geographical coverage and adopting standard techniques of sampling so as to make findings comparable. This will allow detection of early warning signals and regime shifts based on temporal and spatial analyses while providing greater understanding of current and future regulating services of glacier-fed rivers.

iii) Valuation of provisioning, regulating, and cultural ecosystem services associated with glacier-fed systems, in particular considering the implications of emerging concerns about contaminant loads and more detailed understanding of salmon habitat linking to commercial and sport fisheries.

iv) Critical adaptive management decisions in the most sensitive areas to mitigate ecosystem service effects that will have major ramifications for billions of people, with international legislation to protect strategic glacier-derived water resources.
