limited number of mutually specific cohesive sites implied thereby suggests a specialized biological function, one that remains to be identified.

Summary.—The DNA of phage lambda undergoes reversible transitions from linear to characteristically folded molecules, and from linear monomers to open polymers. Some conditions favoring one state or another have been defined. It may be surmised that each molecule carries two specifically interacting cohesive sites.

This work was aided by grant CA-02158 from the National Cancer Institute, National Institutes of Health, U.S. Public Health Service. Its direction was determined in part in conversation with Dr. M. Demerec about heterochromatin, synapsis, deletions, and speculations to be pursued. Professor Bruno Zimm contributed useful suggestions about the manuscript.

ERRATA: ROLE OF CHLOROPHLAST FERREDOXIN IN THE ENERGY CONVERSION PROCESS OF PHOTOSYNTHESIS

BY K. TAGAWA, H. Y. TSUJIMOTO, AND DANIEL I. ARNON

Volume 49, No. 4 (April), pp. 567–572

Page 569: In the final printing, the graphs for Figures 1 and 2 were inadvertently transposed. The graph labeled "Fd-catalyzed photophosphorylations with and without TPN," is Figure 1, but was erroneously shown as Figure 2. The graph labeled "Fd-catalyzed cyclic photophosphorylation" is Figure 2, but was erroneously shown as Figure 1. The text of the legends for Figures 1 and 2 was correctly printed.

Page 571: The first sentence of the last paragraph should read, "It is interesting to note that, although reduced ferredoxin is nonenzymatically oxidized by oxygen, an appreciable leakage of electrons to O2 (O2 is always present around the chloroplasts in vivo) is prevented by the strong affinity of reduced ferredoxin, (a) for the TPN-reducing system, and (b) for the grana-bound electron carriers of cyclic photophosphorylation."
ROLE OF CHLOROPLAST FERREDOXIN IN THE ENERGY CONVERSION PROCESS OF PHOTOSYNTHESIS

By K. Tagawa, H. Y. Tsujimoto and Daniel I. Arnon*

DEPARTMENT OF CELL PHYSIOLOGY, UNIVERSITY OF CALIFORNIA, BERKELEY

Communicated February 27, 1963

Chloroplast ferredoxin,1-4 a water soluble iron protein with a redox potential6 (\(E'_0 = -432\) mV, pH 7.55) close to that of the hydrogen electrode, is the most electronegative constituent isolated so far from the photosynthetic apparatus of green plants. Reduced ferredoxin has recently been identified6 as the earliest, chemically defined reductant formed by chloroplasts at the expense of absorbed radiant energy. These properties are compatible with a role for ferredoxin as an electron carrier in cyclic (eq. 1) and noncyclic (eq. 2) photophosphorylation7-10—the two components of the photosynthetic energy conversion process that produces the assimilatory power (TPNH₂ and ATP11) to drive carbon assimilation by chloroplasts.12-14

\[
\begin{align*}
ADP + P_1 & \xrightarrow{\text{choloroplasts}} \text{ATP} \\
2\text{TPN} + 2\text{ADP} + 2P_1 + 2\text{H}_2\text{O} & \xrightarrow{\text{choloroplasts}} 2\text{TPNH}_2 + 2\text{ATP} + \text{O}_2
\end{align*}
\]

This article reports evidence for a role of ferredoxin in an endogenous type of cyclic photophosphorylation by chloroplasts (eq. 1), which proceeds anaerobically without added cofactors. A requirement for ferredoxin (then called “TPN-reducing factor”11) in noncyclic photophosphorylation (eq. 2) was already observed when this process was first discovered,6 and this requirement has since been further documented.9, 15-17 Evidence was also obtained several years ago3 for a requirement of a “TPN-reducing factor” (i.e., ferredoxin) in what is now called pseudocyclic photophosphorylation18 by chloroplasts, but the significance of these earlier observations for the mechanism of energy conversion in photosynthesis has only now been realized.

Methods.—“Broken” chloroplasts28 (P₁₈ or C₁₈) were used in all experiments. The incandescent light used for illumination was filtered through a Jena G1 or G2 filter, which cut off light of wavelength shorter than 500 μμ. The ATP formed was estimated by the method of Hagihara and Lardy.19 Other experimental procedures were the same as those used previously.28

Results and Discussion.—In the mechanisms currently envisaged in our laboratory,10, 20 cyclic and noncyclic photophosphorylation share the same primary photochemical act which gives rise, within the chloroplasts, to an electron flow from an excited chlorophyll molecule to an endogenous, primary electron acceptor. If, as recent results have shown,6 ferredoxin is the earliest primary electron acceptor that can now be isolated following the photochemical act, then it follows that photo-reduction of ferredoxin should be a common feature of the electron flow pathways of either cyclic or noncyclic photophosphorylation. The two pathways would differ in the electron acceptors beyond ferredoxin. In the case of noncyclic photophosphorylation, the electrons from ferredoxin would be transferred to TPN,
whereas in the case of cyclic photophosphorylation they would "cycle" back to "electron-deficient" chlorophyll molecules via a chain of endogenous electron carriers. (The transfer of electrons from reduced ferredoxin to TPN occurs only in the presence of a flavoprotein reductase which is contained in the chloroplasts.)

If this formulation of the role of ferredoxin is correct, then a transition from non-cyclic to cyclic photophosphorylation should be regulated by the availability of TPN as the electron acceptor. Figure 1 shows that this was experimentally observed. The lowermost curve represents cyclic photophosphorylation in the absence of TPN. The rate of ATP formation by cyclic photophosphorylation was lower than that by noncyclic photophosphorylation in the presence of TPN. Non-cyclic photophosphorylation continued at the higher rate as long as a supply of oxidized TPN was available (uppermost curve). But when all of the available TPN was reduced (middle curve), the more rapid noncyclic photophosphorylation came to an end and the slower cyclic photophosphorylation took its place. The rate of this "delayed" cyclic photophosphorylation was the same as the rate of the initial cyclic photophosphorylation in the absence of TPN (compare the slopes of the middle and lowermost curves in Fig. 1). Where TPN was added (uppermost and middle curves of Fig. 1), its photoreduction was measured spectrophotometrically by absorption at 340 m\(\mu\). The quantities of TPNH\(_2\) found confirmed the stoichiometry of noncyclic photophosphorylation (TPNH\(_2\)/ATP = 1).

The experiments represented by Figure 1 were carried out under aerobic conditions. Forti and Jagendorf and Black et al. have observed that under these conditions ferredoxin ("PPNR") stimulates an endogenous photophosphorylation which proceeds in the absence of added cofactors, but is dependent on, and consumes, molecular oxygen as the terminal electron acceptor. Forti and Jagendorf interpreted their data as ruling out the existence in chloroplasts of a truly endogenous cyclic photophosphorylation, i.e., a phosphorylation that would proceed without the participation of molecular oxygen as the terminal electron acceptor. Evidence was needed, therefore, to show that ferredoxin could catalyze an endogenous cyclic photophosphorylation under anaerobic conditions, when oxygen was initially excluded and its photochemical production effectively prevented.

Evidence for an endogenous ferredoxin-catalyzed cyclic photophosphorylation, which proceeds anaerobically without the addition of other cofactors, was obtained after first establishing the experimental conditions under which this type of photophosphorylation can be observed. These experimental conditions include a relatively low light intensity (illumination higher than 10,000 lux was inhibitory), an optimum pH about 8.2, and the use of \(p\)-chlorophenyl dimethyl urea (CMU) as an inhibitor of oxygen evolution. The significance of these experimental conditions will be discussed in a subsequent publication.

Table 1 shows the dependence of anaerobic cyclic photophosphorylation on the addition of ferredoxin. In other experiments, it was found that under anaerobic conditions the ferredoxin requirement was much greater (up to tenfold) for cyclic photophosphorylation than for the noncyclic type.

As shown in Table 2 the anaerobic cyclic photophosphorylation catalyzed by ferredoxin was strongly dependent on the presence of CMU. In the absence of CMU there was no significant photophosphorylation. The addition of 10 \(\mu\)g of CMU in-
increased the rate of photophosphorylation about sevenfold, but 100 μg of CMU was inhibitory.

Fig. 1.—Transition from noncyclic to cyclic photophosphorylation, catalyzed by ferredoxin (Fd), as influenced by TPN availability.

The reaction mixture contained in a final volume of 4.5 ml, broken chloroplasts (C18) containing 300 μg of chlorophyll, 1,500 μg of spinach ferredoxin and the following in μmoles: tris buffer pH 8.3, 150; MgCl₂, 7.5; ADP, 15; K₂H₃PO₄, 15; and TPN as indicated. The reaction was carried out in 1 cm optical path cuvettes under air at 15°C. Illumination was by incandescent light (10,000 lux) filtered through a Jena G2 filter. At the indicated times, 0.5 ml aliquots of the reaction mixture were withdrawn for ATP determination and 0.3 ml for TPNH₂ determination (see text). The ATP produced is plotted as μmoles ATP in 1.5 ml of reaction mixture.

A notable feature of ferredoxin-catalyzed cyclic photophosphorylation was its sensitivity to antimycin A over a wide range of chlorophyll concentration (Fig. 2). Sensitivity to antimycin A has been observed in the endogenous anaerobic cyclic photophosphorylation by chromatophores of the purple bacteria, Rhodospirillum rubrum²⁴, ²⁵ and Chromatium.²⁶ The inhibition of cyclic photophosphorylation in chromatophores does not occur in the presence of catalytic amounts of phenazine methosulfate,²⁴, ²⁷ which evidently serves as a bypass around the site of antimycin A inhibition. Interestingly enough, the usual type of cyclic photophosphorylation in chloroplasts—measured in the presence of added cofactors and at relatively high chlorophyll concentrations—was also found to be resistant.
to antimycin A inhibition. Since, in mitochondria, antimycin A inhibition is considered to be indicative of the participation of cytochrome b in electron transport, the sensitivity to antimycin A suggests a possible participation of the cytochrome b6 component of chloroplasts in the ferredoxin-catalyzed cyclic photophosphorylation.

Concluding Remarks.—A previously puzzling feature of cyclic photophosphorylation in isolated chloroplasts, a feature which distinguished it from cyclic photophosphorylation in bacterial chromatophores, was a dependence on an added electron carrier such as vitamin K or phenazine methosulfate. A possible, though heretofore experimentally unsupported, explanation of this difference was that chloroplasts, but not chromatophores, automatically lost a soluble constituent in the process of isolation. The present findings point to chloroplast ferredoxin as being the water-soluble constituent of cyclic photophosphorylation which is, at least in part, lost from chloroplasts when they are removed from the cell. However, it is still premature to say what role bacterial ferredoxins play in the mechanism of bacterial photophosphorylation. Differences between the two systems require further study. Thus, it has been found that the pyridine nucleotide-reducing system in chromatophores differs from that in chloroplasts. Chromatophores photoreduce DPN in preference to TPN and do so without the addition of a soluble cofactor such as ferredoxin.

In chloroplasts, ferredoxin appears to be a branching point in the electron transport systems that result either in cyclic or in noncyclic photophosphorylation. Since TPN is required for noncyclic photophosphorylation but not for cyclic photophosphorylation, it follows that when photoreduced ferredoxin is reoxidized by TPN (with the aid of an appropriate flavoprotein enzyme), noncyclic photophosphorylation would result. When oxidized TPN is unavailable

Experimental conditions were as described in the legend for Table 1 except that 1,500 µg of spinach ferredoxin were used throughout. CMU was added as indicated.
as an electron acceptor, the photoreduced ferredoxin would be reoxidized by a bound component of the grana, and cyclic photophosphorylation would result. It is thus possible to envisage that the availability of TPN as an electron acceptor would serve as a physiological regulator between cyclic and noncyclic photophosphorylation. TPN availability would, in turn, be regulated by the reoxidation of TPNH₂ in the course of reductive carbon assimilation (cf. ref. 8).

It is interesting to note that, although reduced ferredoxin is nonenzymatically oxidized by oxygen,⁵ an appreciable leakage of electrons to O₂ (is always present around the chloroplasts in vivo) is prevented by the strong affinity of reduced ferredoxin, (a) for the TPN-reducing system, and (b) for the grana-bound electron carriers of cyclic photophosphorylation. We have observed, even under aerobic conditions, a cyclic photophosphorylation in isolated chloroplasts that was essentially independent of molecular oxygen as the terminal electron acceptor. A more detailed discussion of this point will be presented elsewhere.

⁵ Ferredoxin of chloroplasts is the same substance as the methemoglobin-reducing factor of Davenport, Hill, and Whatley,⁶ the TPN-reducing factor of Arnon, Whatley, and Allen,⁷ and the photosynthetic pyridine nucleotide reductase (PPNR) of San Pietro and Lang.⁸ This change in nomenclature, discussed in more detail elsewhere,⁹ is based on the recently discovered chemical and functional similarities of ferredoxins from bacteria and chloroplasts.

Abbreviations: ATP, adenosine triphosphate; ADP, adenosine diphosphate; Pₐ, orthophosphate; TPN, TPNH₂, oxidized and reduced forms of triphosphopyridine nucleotide; DPN, diphosphopyridine nucleotide.

THE DEFECTIVENESS OF ROUS SARCOMA VIRUS*

BY HIDESABURO HANAFUSA, TERUKO HANAFUSA, AND HARRY RUBIN

VIRUS LABORATORY, UNIVERSITY OF CALIFORNIA, BERKELEY.

Communicated by Robley C. Williams, February 19, 1963

The Bryan high-titer strain of Rous sarcoma virus (RSV) produces foci of transformed cells after infecting monolayers of chick embryo cells in tissue culture. The transformed cells take on the typical rounded appearance of cultivated Rous sarcoma cells and are no longer restricted to growth in a monolayer. When a stock of RSV is diluted beyond the end point for focus formation, another virus can readily be isolated which has been called Rous-associated virus (RAV). RAV does not cause a noticeable morphological change in cells, but it induces resistance to RSV within a few days, and this resistance is the basis for the assay of RAV. RAV is indistinguishable from RSV in heat sensitivity, cellular site of maturation, growth rate, and immunological specificity. It is known to differ from RSV only in its failure to produce either foci in tissue culture or sarcomas in the chicken. It does, however, produce leukosis in chickens, and can be considered a virus of the avian leukemia complex. In view of its close relationship to RSV and its presence in RSV stocks in higher titer than RSV itself, it seemed unlikely that RAV was a mere accidental contaminant of the RSV stock. A study was undertaken to clarify the relationship of the two viruses. Attempts were made to isolate a stock of RSV free of RAV by picking single foci of transformed cells. Although the transformed cells present in such foci multiplied indefinitely and maintained their distinctive morphology, they failed to produce either RSV or RAV. However, when RAV was added to such cells, they quickly produced large amounts of both RAV and RSV. We conclude from these observations that RSV is a defective virus which can only produce mature virus in the presence of a helper virus such as RAV.

Material and Methods.—RSV stock and assay: The high titer strain of RSV was used in the present studies. The stock was obtained from the medium of heavily infected monolayers of chick embryo cells. The medium was subjected to sonic vibration at 9 kc to disperse virus aggregates. The virus titer was assayed by focus formation on chick embryo cells. The RSV stock contained 5 \( \times 10^6 \) focus forming units (FFU) of RSV per ml and about 5 \( \times 10^6 \) infectious units of RAV per ml (see below).

RAV stock and assay: RAV was isolated from a stock of RSV and was purified twice by limiting dilution in vitro. The stock used was obtained by disrupting infected chick embryo cells by sonic vibration. The virus was assayed by its interference with RSV infection as described...
