Communicated by Roscoe O. Brady, National Institute of Neurological Disorders and Stroke, Bethesda, MD, September 3, 1997 (received for review July 7, 1997)

ABSTRACT Little is known about the potential for engraftment of autologous hematopoietic stem cells in human adults not subjected to myeloablative conditioning regimens. Five adult patients with the p47phox deficiency form of chronic granulomatous disease received intravenous infusions of autologous CD34+ peripheral blood stem cells (PBSCs) that had been transduced ex vivo with a recombinant retrovirus encoding normal p47phox. Although marrow conditioning was not given, functionally corrected granulocytes were detectable in peripheral blood of all five patients. Peak correction occurred 3–6 weeks after infusion and ranged from 0.004 to 0.05% of total peripheral blood granulocytes. Corrected cells were detectable for as long as 6 months after infusion in some individuals. Thus, prolonged engraftment of autologous PBSCs and continued expression of the transduced gene can occur in adults without conditioning. This trial also piloted the use of animal protein-free medium and a blood-bank-compatible closed system of gas-permeable plastic containers for culture and transduction of the PBSCs. These features enhance the safety of PBSCs directed gene therapy.

Chronic granulomatous disease (CGD) is a rare inherited disorder of phagocytes associated with recurrent life-threatening infections (1, 2). CGD is caused by a defect in the phagocyte NADPH oxidase (phox) that normally generates superoxide. When normal phagocytes engulf opsonized pathogens, the oxidase becomes activated by translocation of three cytoplasmic proteins (p47phox, p67phox, and rac-2) to the cell membrane where they bind to flavocytochrome b558 (a heteromeric transmembrane protein composed of two peptides, gp91phox and p22phox) (3, 4). The genetic basis of CGD is heterogeneous (1, 5). The most common form (about two-thirds of the cases) is X chromosome-linked, resulting from mutations in the gp91phox gene. The next most common form (about one-third of the cases) is autosomal recessive resulting from mutations in the p47phox gene on chromosome 7 (2, 4). The remaining 5% of cases are due to mutations in the genes encoding p22phox (chromosome 16) or p67phox (chromosome 1).

Bone marrow transplantation can cure CGD (6, 7), indicating that the stem cells giving rise to granulocytes and monocytes are an appropriate target for gene therapy. Bone marrow transplantation in CGD has been associated with unacceptable high rates of morbidity, mortality, and graft failure, except in the case of HLA-matched sibling donors (6, 7). Specific gene therapy of autologous peripheral blood stem cells (PBSCs) would avoid these problems. The feasibility of genetic correction of CGD with retrovirus vectors has been demonstrated ex vivo by transduction of human CD34+ PBSCs from patients with each of the four forms of CGD (8–10). Furthermore, genetic correction of the gp91phox and p47phox deficiency forms of CGD has been demonstrated in vivo after stem-cell gene therapy of gene knockout CGD mice and is associated with an increased resistance to infection (11, 12).

In the CGD mouse gene therapy studies, total body radiation was used as a conditioning regimen to enhance engraftment of gene-corrected stem cells. Although partial marrow ablation has been thought to be required to optimize engraftment of infused hematopoietic stem cells even in the autologous setting, a number of animal studies using syngeneic cells have suggested that infusion of large numbers of stem cells can partially overcome this barrier (13). In this clinical trial of gene therapy, we examine the potential for engraftment of transduced-gene-corrected autologous CD34+ stem cells in adult patients with the p47phox deficiency form of CGD (p47phox CGD) without marrow conditioning.

MATERIALS AND METHODS

Patients and Consent Documents. Patients 1 to 5 have p47phox CGD as demonstrated by history of recurrent infections, by phagocytic cells that lack both oxidase activity and p47phox protein, and by p47phox gene mutation analysis (14, 15). Patients 1 and 2 are Caucasian and are, respectively, female, male, female, male, female, and years of age at study entry were 37, 21, 18, 27, and 27. A gene-therapy phase I protocol with associated informed consent document was reviewed and approved by the National Institute of Allergy and Infectious Disease human investigation review board (Protocol 95-I-0134), by the National Institutes of Health Biosafety Committee (Approval document RD-94-XI-05), by the National Institutes of Health Recombinant DNA Advisory Committee (Protocol 9503–104), and by the U.S. Food and Drug Administration (BB IND 6100).

Protocol Clinical Procedures. Beginning on study day 1, patients were given six daily subcutaneous injections with granulocyte colony-stimulating factor (Amgen) at 10 µg/kg to mobilize CD34+ PBSCs from the marrow (16). On both study days 5 and 6, a 10- to 15-liter apheresis stem cell collection was performed by using the CS3000 Plus blood cell separator.

Abbreviations: PBSC, peripheral blood stem cell; CGD, chronic granulomatous disease; phox, phagocyte NADPH oxidase; PMA, phorbol myristate acetate; NBT, nitroblue tetrazolium dye; DHR, dihydrorhodamine 123.

(Baxter Healthcare, Fenwal Division, Deerfield, IL) with manufacturer recommended settings. On study days 8 and 9, the purified cultured and transduced PBSCs derived from the apheresis products were administered intravenously.

**Purification of CD34+ PBSCs.** CD34+ PBSC enrichment from the apheresis product was performed by using the ISOLEX 300 SA immunomagnetic stem cell selection system (Baxter Healthcare, Immunotherapy Division, Irvine, CA). The purification procedure using this device was performed by the manufacturer’s instructions. Briefly, CD34+ PBSCs were labeled with murine anti-CD34 mAb and the labeled cells were magnetically captured by using paramagnetic beads containing surface-bound sheep anti-mouse IgG. CD34+ cells were released from the paramagnetic beads by epinephrine competition by using a peptide that mimics the CD34 epitope as a releasing agent. In some cases, a few additional CD34+ cells could be released from the beads enzymatically by using chymopapain. CD34+ PBSCs were enumerated by fluorescent antibody flow cytometry analysis (16).

**Closed Container System for Handling and Culturing CD34+ PBSCs.** Purified CD34+ PBSCs were handled, cultured, and transduced in a closed system of plastic containers that could be connected steriley by using a Terumo SCD 312 sterile tubing welder (Baxter, Fenwal Division). Three types of plastic containers were used. Polyvinyl chloride (PL-146) containers (Baxter, Fenwal Division) with limited gas permeability were used to store medium. CD34+ PBSCs were cultured in gas-permeable stem cell culture (PL-2417) containers (Baxter, Immunotherapy Division) that are optimized for growth of PBSCs. Because of differences in tensile properties and construction, the early prototype PL-2417 containers for this study were not centrifuged, but instead Life Cell gas-permeable (PL-732) containers (Baxter, Immunotherapy Division) designed for lymphocyte culture were used to centrifuge cells.

**Production of Clinical Grade Retrovirus Encoding p47phox.** The ORF of human p47phox cDNA (17, 18) was inserted into the MFGS retrovirus vector (Cell Genesys, Foster City, CA) (8–10). MFGS-p47phox plasmid was transfected into the amphotropic envelope packaging line ψ-CRIP, and a vector-producing clone was selected (8–10). For production of cGMP (U.S. Food and Drug Administration current good manufacturing practice) clinical lots of retrovirus supernatant (Cell Genesys), the producer was expanded in DMEM/10% calf serum and then washed with and switched to a serum-free and animal-protein-free medium (X-VIVO 10; BioWhittaker) containing 1% human serum albumin (Baxter Healthcare, Hyland Division, Glendale, CA) for each 8-hr retrovirus supernatant harvest.

**PBSC Culture and Transduction Procedures.** On the day of apheresis (culture day 0) purified CD34+ PBSCs were suspended at 0.5 to 2 × 10^6 cells per ml in PBSC growth medium that was serum-free and animal-protein-free (X-VIVO 10 containing 1% human serum albumin and Piyxine [PIXY321; interleukin 3/ granulocyte–macrophage colony-stimulating factor fusion protein from Immunex]) at 100 ng/ml and granulocyte colony-stimulating factor (Amgen) at 10 ng/ml. PBSCs were cultured overnight in a PL-2417 gas-permeable container in 7% CO_2/93% air at 37°C. The next morning (culture day 1) the cells were transferred to a PL-732 container, centrifuged, and resuspended into 50% vector supernatant (titer ~10^6 transducing units/ml) containing the same growth factor concentrations and at the same cell concentration as for overnight culture. Cells were spin-transduced at 1,200 × g at 32°C for 1 hr (10) and incubated 5 hr at 37°C, 7% CO_2/93% air, after which cells were transferred back to PBSC growth medium in the PL-2417 container over-night. The transduction procedure was repeated on culture days 2 and 3 after which the cells were washed and resuspended in Plasmalyte (Baxter, Hyland Division) containing 1% human serum albumin for intravenous administration. Samples of cells were retained in liquid culture or plated in agarose for further analysis. Cultures of nontransduced PBSCs from the patients and PBSCs from normal volunteers (Human Investigation Review Board approved National Institutes of Health Protocol 94-I-0073) served as negative and positive controls for assays of oxidase activity.

**Analysis of Transduction and Correction of Oxidase Activity.** At the end of culture day 3, PBSCs were plated in agarose to allow formation of myeloid colonies, which were evaluated for oxidase activity by using a phorbol 12-myristate 13-acetate (PMA)-stimulated nitroblue tetrazolium dye (NBT) test (8, 10). Myeloid colonies demonstrating intense staining with the formazan precipitate were scored as positive. CD34+ cells were maintained in liquid culture for 17 days and analyzed for PMA-stimulated superoxide production by using a chemiluminescence assay (8–10). SDS/PAGE and immunoblotting were used to detect production of p47phox protein in these cells (8, 10).

A flow cytometry assay of oxidant production using dihydrodorhamine 123 (DHR) loading of the cells also was performed (10, 12, 19, 20). At day 17, liquid cultures of normal CD34+ PBSCs undergoing differentiation contained 10–12% granulocytes, which are the only cells that fluoresce brightly in the flow cytometry DHR assay after PMA stimulation (10). The DHR assay also was used to detect oxidase-positive neutrophils in vitro in the peripheral blood of patients after gene therapy (19, 20). Correction of peripheral blood neutrophils also was evaluated visually by NBT staining (21).

Vector copy number in the ex vivo-transduced CD34+ PBSCs was determined by Southern blot hybridization (22), and a PCR assay was used for detection of transduced p47phox cDNA present in vivo in peripheral blood leukocyte genomic DNA (23, 24). For the PCR assay, nested oligonucleotide primers derived from p47phox cDNA sequence were designed to overlap exon junctions (14, 15) and were found empirically to amplify p47phox cDNA sequence but not genomic sequence. The outer primer pairs are AGC AACTG TGTACAGTG TCC (bp 65–85, exons 1/2) and GAGTATGCTAC/ CTCGATAGTTG (bp 696–672, exons 8/7). The inner primer pairs are CTACGAGTTCC/AAACC (bp 140–169, exons 2/3) and CCGGTGATG/CTGTCGCCG (bp 481–443, exons 5/4). Two detecting methods were used. The inner primer pair was used to produce a labeled sequence to probe the outer primer pair PCR product by Southern blotting or was used in a second PCR to amplify a specific nested PCR sequence from the first PCR product (24).

**Safety Testing of Patient Blood.** Because all five patients have a protein null phenotype of p47phox CGD, patient serum was tested for the development of antibody specific to p47phox by SDS/PAGE and immunoblot (8) detection of recombinant p47phox. Genomic DNA from patient peripheral blood cells was screened for the presence of replication competent retrovirus by using a PCR assay to detect sequence encoding amphotropic envelope (22, 24).

**RESULTS**

**Ex Vivo Culture and Transduction of CD34+ PBSCs in Serum-Free Medium and Gas-Permeable Containers.** Patients were free of active infection at study entry, though patient 1 had recovered recently from a pneumonia. Blood studies were within normal limits except for mild anemia (all hematocrits were <26). As expected (16), granulocyte colony-stimulating factor mobilization of CD34+ cells to the peripheral blood of CGD patients was modest and varied among CGD patients. By day 5, the concentration of CD34+ cells had increased from baseline levels below two cells per μl in all patients to a level in patients 1 to 5 of 53, 27, 22, 81, and 13 CD34+ cells per μl, respectively. Despite the apheresis procedure on day 5, these counts were similar at the time of the day 6 apheresis. Ten apheresis products were collected (2 per patient) averaging 35 ± 3.7 × 10^6 mononuclear cells per product (mean ± SEM). After ISOLEX immunoaffinity selection, a mean of 125 ±
23.6 × 10^6 cells (n = 10) was recovered, at a median purity of 80% CD34+ cells resulting in a median yield of 38%.

After the 3 days of culture and transduction, each patient received two autologous products (Table 1, preparations A and B) without any symptoms or changes in vital signs. The total number of cells infused ranged from 0.1 to 4.7 × 10^6 cells per kg (Table 1). Transduced PBSCs averaged 91 ± 2.7% cell viability, had a colony plating efficiency of 104 ± 38.4 colonies per 1,000 cells plated, and passed safety testing for sterility, endotoxin, and replication competent retrovirus. SDS/PAGE and immunoblotting demonstrated a strong positive signal for the presence of recombinant p47phox protein in all of the transduced CGD PBSC cultures (Fig. 1, lanes B and C). Shown in Table 1 are studies performed on each product to assess the percent of cells expressing CD34 antigen on culture day 3, correction of oxidase activity by chemiluminescence and DHR assays on culture day 17, the percent of myeloid-colony-forming progenitors plated on day 3 giving rise to oxidase-positive colonies, and the vector copy number in the transduced PBSCs. The data are consistent with preservation of a primitive phenotype and a high rate of gene transfer and functional correction 

![Image: Correction of p47phox protein deficiency ex vivo. These are SDS/PAGE immunobots demonstrating detection of p47phox protein in transduced or control CD34+ PBSCs at culture day 17. The results for studies of patients 1 to 5 are shown from the top to bottom, as indicated. Shown in lanes A are the analyses of nontransduced cultured CD34+ PBSCs from each patient and as expected no signal is detected. Shown in lanes B and C are the analyses of cultured and MFGS-p47phox-transduced CD34+ PBSCs derived from the first and second apheresis products from each patient. Shown in lanes D as a positive control in each case is an analysis of nontransduced normal control CD34+ PBSCs cultured in parallel with the patient cells.](image)

**Presence of NADPH Oxidase-Positive Neutrophils in the Peripheral Blood After Intrauterine Administration of Ex Vivo Transduced Autologous CD34+ PBSCs.** The flow cytometry DHR assay was used to measure the appearance of NADPH oxidase-positive granulocytes in the peripheral blood after gene therapy. The dot plot shown in Fig. 2A demonstrates that the events generated from analysis of PMA-stimulated normal peripheral blood granulocytes cluster in a tight band at the right side of the graph, consistent with robust oxidase activation. As shown in Fig. 2B, analysis of PMA-stimulated blood granulocytes from patient 1 before gene therapy resulted in all but a single event to the left of the “positive threshold” line, characteristic of absent oxidase function. At day 24 after gene therapy, PMA-stimulated peripheral blood granulocytes from patient 1 generated almost 80 events appearing to the right of the “positive threshold” line in a tight cluster (Fig. 2C) with mean fluorescence intensity (x axis) similar to that of granulocytes from the normal control (compare Fig. 2A and C). Although the number of corrected cells is small, the data indicate that these gene corrected granulocytes from patient 1 have acquired oxidase activity similar to normal cells. Qualitatively similar results were obtained for the other four patients. To confirm the results of the DHR assay by direct visualization of individual neutrophils, an NBT stain of PMA-stimulated peripheral blood neutrophils was performed. In the example shown in Fig. 3 with blood from patient 1 at day 26 after gene therapy, 1 in 2,000 granulocytes was oxidase-positive, consistent with the count determined by DHR assay as reported in Fig. 4.

Each patient was followed over time for detection of corrected granulocytes in peripheral blood (Fig. 4). In each subject no oxidase-corrected granulocytes were detected for at least 2 weeks

*Each patient received two preparations (Prep, A and B) of the transduced and cultured PBSCs derived from the first and second apheresis procedures, respectively.

At culture day 3 for each preparation, the number of cells shown (×10^6) were infused intravenously. Shown in the parentheses is the total number of cells (×10^6) (A plus B) infused per kg of body weight.

Measured by flow cytometry analysis at the end of culture day 3.

Assays were performed on day 17 of culture.

Cells were plated at culture day 3 and assayed 14 days later.

Measured by Southern blot of genomic DNA from the transduced and cultured PBSCs, probed with a MFGS-vector-specific 5’ long terminal repeat sequence and a cell line with known vector copy number of 1 as a reference.
DISCUSSION

Our data demonstrate the appearance of gene-corrected oxidase-positive granulocytes in the peripheral blood of each of five patients with p47phox CGD after PBSC-targeted gene therapy with vector encoding p47phox. In patient 1, we also demonstrated that the gene-corrected oxidase-positive neutrophils could migrate from the circulation to a site of infection. Moreover, the kinetics of appearance of these functionally corrected granulocytes share similar characteristics in all patients. In all patients, the first appearance of oxidase-positive granulocytes required at least 2 weeks, suggesting that engulfment, proliferation, and differentiation of the transduced PBSCs in the marrow was required. In all patients, there was an initial wave of oxidase-positive cells first peaking at 22–39 days followed by one or more waves (usually of much smaller magnitude) of oxidase-positive cells at intervals out to 6 months in some individuals. If this periodicity is real, it could be evidence of clonal succession where only a small subset having the shortest duration and patient 2 having the lowest peak number of corrected granulocytes. Patients 1 to 5 have now been followed after gene therapy for 25, 23, 22, 21, and 20 months (as of August 1997), respectively, but no oxidase-positive cells have been seen in any peripheral blood DHR assay after the last data points shown in Fig. 4. PCR detection of the transduced p47phox cDNA was performed on genomic DNA isolated from peripheral blood leukocytes as shown in Table 2 and confirms that a transient low level of gene marking of peripheral blood leukocytes occurred.

Results of Safety Studies and Long-Term Clinical Follow Up.

PCR assay of amphotropic envelope sequence failed to detect evidence of replication-competent retrovirus in peripheral blood leukocytes at 1, 3, 6, and 9 months after gene therapy. Similarly, serum samples were negative for anti-p47phox antibodies at 1 and 3 months after gene therapy. All five patients are currently stable without infection. Except for patient 1, the other four patients have had no deep tissue infections during the follow-up period, and hematologic, renal, and liver function tests are normal. Patient 1 had severe Burkholderia cepacia pneumonia 3 weeks after gene therapy, from which she recovered. During her pneumonia oxidase-positive neutrophils were detected in an empyema by flow cytometry DHR assay and NBT stain, demonstrating that these gene therapy corrected cells were capable of migrating to an inflammatory focus. It is possible that host responses to this infection affected the peak level of gene corrected granulocytes seen in this individual.
permanent high-level engraftment of autologous-gene-marked hematopoietic stem cells can be achieved in nonconditioned older children or adults, where gene transfer provides no selective growth advantage.

We have demonstrated in a congenic mouse model system that low-dose nonablative radiation conditioning can increase greatly the engraftment of congenic marrow stem cells in a radiation dose-dependent manner (32). This suggests the possibility that acceptable regimens of marrow conditioning may be developed for hematopoietic-stem-cell-targeted gene therapy. Such conditioning might increase the level of gene marking from that seen in our current study to levels that could provide prolonged clinical benefit.

The DHR assay of oxidase function provides strong evidence that low-level prolonged engraftment of gene-marked hematopoietic progenitors can occur in human adults without marrow ablation or conditioning. Though the PCR confirmed this, PCR was not sensitive enough to detect marking at later time points where the flow cytometry DHR assay continued to indicate lower levels of oxidase-positive neutrophils. The PCR data demonstrate that the eventual disappearance of gene-corrected oxidase-positive granulocytes by DHR assays was not associated with continued presence in the peripheral blood of substantial numbers of leukocytes marked with a nonfunctional transduced gene.

Although we cannot exclude the possibility that silencing of transcription of the transduced oxidase gene is occurring, the data are more consistent with disappearance of transduced cells. This might happen if very early progenitors rather than permanently repopulating stem cells were targeted. Several published human clinical studies of hematopoietic-stem-cell-targeted gene transfer (26, 27, 30, 31) have demonstrated low-level engraftment of retrovirus-transduced gene in blood or marrow cells by using PCR. Although these studies indicate the presence of the transduced gene, assessment of gene function in the host, as in our study and others (33), provides an important additional insight regarding the clinical potential for gene therapy. How to target the most primitive stem cells and how to prevent transcription silencing in vivo remain important issues to resolve in future studies.

An additional goal of this clinical trial was to develop and pilot the use of materials and methods that increase the safety of ex vivo gene therapy targeting hematopoietic stem cells. Animal proteins, including fetal calf serum, are widely used as required supplements to most cell culture media. Animal proteins internalized by human cells during prolonged culture may not be removed by centrifugation washing and can stimulate an immune response (34). Because gene therapy is in an early developmental stage, it is likely that any patients participating in these initial
studies will be treated again in the future at a time when such treatments are more efficient. If it is at all possible to limit exposure to animal proteins, particularly fetal calf serum, in these early studies without compromising the scientific goals of the study, then such a safety feature should be incorporated into the protocol. A second important safety feature incorporated into this study was a closed system of gas-permeable flexible plastic containers for culture and transduction. The closed system reduces the contamination risk associated with pipetting cells and medium yet allows such handling to become a counter-top process. Biosafety cabinets are required at only a few steps and the system is compatible with techniques already used widely in most blood banks. We demonstrate that it is possible to incorporate these safety features without compromising PBCV viabilities or transduction efficiencies.

The clinical potential of gene therapy is yet to be realized, and there has been considerable interest in defining both the scientific and clinical goals of human trials of gene transfer. In the case of CGD, where life-threatening infections may require many weeks or months of therapy and relapses are frequent, use of gene therapy to provide even short- to medium-term production of oxidase-positive autologous granulocytes may be clinically beneficial. This concept is supported by published studies of gene therapy in mouse models of both the X chromosome-linked (gp91phox-deficiency) and p47phox-deficiency forms of CGD that demonstrate that even transient partial correction of the oxidase defect is associated with some protection against infection challenge (11, 12). Furthermore, in human female carriers of the X chromosome-linked form of CGD, the X chromosome inactivation that occurs during embryogenesis results in phenotypic expression of X chromosome-linked CGD carriers can be found who have only 3% to 5% oxidase-positive blood (21). Because this is a stochastic process, some female oxidase-negative granulocytes can be detected in the peripheral blood (21). Because this is a stochastic process, some female carriers can be found who have only 3% to 5% oxidase-positive neutrophils yet do not suffer from an increased incidence of infection. The knockout mouse studies and the clinical observations of X chromosome-linked CGD carriers suggest that even a short-term low level of gene correction in CGD could be clinically beneficial for treatment of severe prolonged infections. Until the tools are developed to achieve high-level permanent gene transfer to hematopoietic cells, our studies suggest that an achievable intermediate goal of development of gene therapy for CGD might be to augment neutrophil function in the treatment of severe infections.

Somatic Therapy Corporation, an industrial collaborator during the conduct of this study, is now a part of Cell Genesys. We thank Immunex for providing Pexyine for ex vivo culture of CD34+ PBSCs. We are grateful for the important contributions of the National Institute of Allergy and Infectious Diseases 11 East day hospital staff and the National Institutes of Health transfusion medicine apheresis staff. We thank Dr. Stephen Chanock for doing the p47phox mutation analysis of our patients. We thank Dr. Philip Murphy for critical reading of the manuscript and Dr. Douglas Kuhns for preparing Fig. 3. Finally, we thank the participating patients and the physicians who served as physician-advocates for their patients during the informed consent process.
