

## Vitamin B deficiency causes neural cell loss and cognitive impairment in the developing rat

The article by Troen *et al.* (1) adds interesting evidence that vitamin-B deficiency is associated with selective brain damage and cognitive decline. It reports a rarefaction of hippocampal microvasculature without neurodegeneration or gliosis in male C57BL/6/J mice fed a B-vitamin-deficient diet. Cognitive impairment was shown by using a Morris water maze. According to the authors, this may result from the microvascular rarefaction. In a recent article (2) we showed that rat pups from dams fed a diet lacking methyl precursors (folate, vitamin B12, choline) during gestation and lactation accumulated homocysteine (direct measurement and immunohistochemistry), with decreased S-adenosylhomocysteine, in both neurons and astrocytes of selective brain structures, namely hippocampus, cerebellum, striatum, and the neurogenic subventricular zone. However, the influence of B-vitamin deficiency on neurodegeneration and neurogenesis is a matter of debate (3–5). In agreement with Troen *et al.* (1), we observed a 48% reduction of the thickness of the CA1 pyramidal layer (Fig. 1 *Upper*) without noticeable gliosis in our developing rat model. Homocysteine-positive neurons expressed p53 and displayed fragmented DNA, indicative of apoptosis. In addition, further investigations showed that neurogenesis was only slightly affected in the dentate gyrus of deficient rats, but not in the subventricular zone (Fig. 1 *Lower*). Also, early vitamin B deprivation was associated with long-lasting functional disabilities of exploratory behavior (elevated plus maze) and learning and memory capacities (8-arm maze) at 80 days of age, long after switch to normal food. This suggests that vitamin B deprivation in early life may produce selective and persisting brain defects consistent with neurodegeneration.
