The ability to learn tasks in a sequential fashion is crucial to the development of artificial intelligence. Until now neural networks have not been capable of this and it has been widely thought that catastrophic forgetting is an inevitable feature of connectionist models. We show that it is possible to overcome this limitation and train networks that can maintain expertise on tasks that they have not experienced for a long time. Our approach remembers old tasks by selectively slowing down learning on the weights important for those tasks. We demonstrate our approach is scalable and effective by solving a set of classification tasks based on a hand-written digit dataset and by learning several Atari 2600 games sequentially.

A
chieving artificial general intelligence requires that agents are able to learn and remember many different tasks (1). This is particularly difficult in real-world settings: The sequence of tasks may not be explicitly labeled, tasks may switch unpredictably, and any individual task may not recur for long time intervals. Critically, therefore, intelligent agents must demonstrate a capacity for continual learning: that is, the ability to learn consecutive tasks without forgetting how to perform previously important tasks. We demonstrate our approach is scalable and effective by solving a set of classification tasks based on a hand-written digit dataset and by learning several Atari 2600 games sequentially.

In marked contrast to artificial neural networks, humans and other animals appear to be able to learn in a continual fashion (11). Recent evidence suggests that the mammalian brain may avoid catastrophic forgetting by protecting previously acquired knowledge in neocortical circuits (11–14). When a mouse acquires a new skill, a proportion of excitatory synapses are strengthened; this manifests as an increase in the volume of individual dendritic spines of neurons (13). Critically, these enlarged dendritic spines persist despite the subsequent learning of other tasks, accounting for retention of performance several months later (13). When these spines are selectively “erased,” the corresponding skill is forgotten (11, 12). This provides causal evidence that neural mechanisms supporting the protection of these strengthened synapses are critical to retention of task performance. These experimental findings—together with neurological models such as the cascade model (15, 16)—suggest that continual learning in the neocortex relies on task-specific synaptic consolidation, whereby knowledge is durably encoded by rendering a proportion of synapses less plastic and therefore stable over long timescales.

In this work, we demonstrate that task-specific synaptic consolidation offers a unique solution to the continual-learning problem for artificial intelligence. We develop an algorithm analogous to synaptic consolidation for artificial neural networks, which we refer to as elastic weight consolidation (EWC). This algorithm slows down learning on certain weights based on how important they are to previously seen tasks. We show how EWC can be used in supervised learning and reinforcement learning problems to train several tasks sequentially without forgetting older ones, in marked contrast to previous deep-learning techniques.

Significance

Deep neural networks are currently the most successful machine-learning technique for solving a variety of tasks, including language translation, image classification, and image generation. One weakness of such models is that, unlike humans, they are unable to learn multiple tasks sequentially. In this work we propose a practical solution to train such models sequentially by protecting the weights important for previous tasks. This approach, inspired by synaptic consolidation in neuroscience, enables state of the art results on multiple reinforcement learning problems experienced sequentially.

Results

EWC. In brains, synaptic consolidation might enable continual learning by reducing the plasticity of synapses that are vital to previously learned tasks. We implement an algorithm that performs a similar operation in artificial neural networks by constraining important parameters to stay close to their old values. In this section, we explain why we expect to find a solution to a new task in the neighborhood of an older one, how we implement the constraint, and finally how we determine which parameters are important.

A deep neural network consists of multiple layers of linear projection followed by element-wise nonlinearities. Learning a task consists of adjusting the set of weights and biases \( \theta \) of the linear projections, to optimize performance. Many configurations of \( \theta \) will result in the same performance \([17, 18]\); this overparameterization makes it likely that there is a solution for task \( B \), \( \theta^*_B \), that is close to the previously found solution for task \( A \), \( \theta^*_A \). While learning task \( B \), EWC therefore protects the performance in task \( A \) by constraining the parameters to stay in a region of low error for task \( A \) centered around \( \theta^*_A \), as shown schematically in Fig. 1. This constraint is implemented as a quadratic penalty and can therefore be imagined as a spring anchoring the parameters to the previous solution, hence having the name elastic. Importantly, the stiffness of this spring should not be the same for all parameters; rather, it should be greater for parameters that most affect performance in task \( A \).

To justify this choice of constraint and to define which weights are most important for a task, it is useful to consider neural network training from a probabilistic perspective. From this point of view, optimizing the parameters is tantamount to finding their most probable values given some data \( D \). We can compute this conditional probability \( p(\theta|D) \) from the prior probability of the parameters \( p(\theta) \) and the probability of the data \( p(D) \) by using Bayes’ rule:

\[
\log p(\theta|D) = \log p(D|\theta) + \log p(\theta) - \log p(D).
\]  

[1]

Note that the log probability of the data given the parameters \( \log p(D|\theta) \) is simply the negative of the loss function for the problem at hand \( -L(\theta) \). Assume that the data are split into two independent parts, one defining task \( A \) \((D_A)\) and the other defining task \( B \) \((D_B)\). Then, we can rearrange Eq. 1:

\[
\log p(\theta|D) = \log p(D_B|\theta) + \log p(\theta|D_A) - \log p(D_B).
\]  

[2]

Note that the left-hand side is still describing the posterior probability of the parameters given the entire dataset, whereas the right-hand side depends only on the loss function for task \( B \), \( \log p(D_B|\theta) \). All of the information about task \( A \) must therefore have been absorbed into the posterior distribution \( p(\theta|D_A) \). This posterior probability must contain information about which parameters were important to task \( A \) and is therefore the key to implementing EWC. The true posterior probability is intractable, so following the work on the Laplace approximation by Mackay \([19]\), we approximate the posterior as a Gaussian distribution with mean given by the parameters \( \theta^*_A \) and a diagonal precision given by the diagonal of the Fisher information matrix \( F \). \( F \) has three key properties \([20]\): (i) It is equivalent to the second derivative of the loss near a minimum, (ii) it can be computed from first-order derivatives alone and is thus easy to calculate even for large models, and (iii) it is guaranteed to be positive semidefinite. Note that this approach is similar to expectation propagation where each subtask is seen as a factor of the posterior \((21)\). Given this approximation, the function \( L \) that we minimize in EWC is

\[
L(\theta) = L_B(\theta) + \sum_i \lambda \frac{1}{2} F_i (\theta_i - \theta^*_{A,i})^2,
\]  

[3]

where \( L_B(\theta) \) is the loss for task \( B \) only. \( \lambda \) sets how important the old task is compared with the new one, and \( i \) labels each parameter.

When moving to a third task, task \( C \), EWC will try to keep the network parameters close to the learned parameters of both tasks \( A \) and \( B \). This can be enforced either with two separate penalties or as one by noting that the sum of two quadratic penalties is itself a quadratic penalty.

EWC Extends Memory Lifetime for Random Patterns. As an initial demonstration, we trained a linear network to associate random (i.e., uncorrelated) binary patterns to binary outcomes. Whereas this problem differs in important ways from more realistic settings that we examine later, this scenario admits analytical solutions and thus provides insights into key differences between EWC and plain gradient descent. In this case, the diagonal of the total Fisher information matrix is proportional to the number of patterns observed; thus in the case of EWC the learning rate lowers as more patterns are observed. Following ref. 15, we define a memory as retained if its signal-to-noise ratio (SNR) exceeds a certain threshold. Fig. 2, Top shows the SNR obtained using gradient descent (blue lines) and EWC (red lines) for the first pattern observed. At first, the SNR in the two cases is very similar, following a power-law decay with a slope of \(-0.5\). As the number of patterns observed approaches the capacity of the network, the SNR for gradient descent starts decaying exponentially, whereas EWC maintains a power-law decay. The exponential decay observed with gradient descent is due to new patterns interfering with old ones; EWC protects from such interference and increases the fraction of memories retained (Fig. 2, Bottom).

In the next sections we show that in more realistic cases, where input patterns have more complex statistics, interference occurs more easily with consequently more striking benefits for EWC over gradient descent.

EWC Allows Continual Learning in a Supervised Learning Context. We next addressed the problem of whether EWC could allow deep neural networks to learn a set of more complex tasks without catastrophic forgetting. In particular, we trained a fully connected multilayer neural network on several supervised learning
tasks in sequence. Within each task, we trained the neural network in the traditional way, namely by shuffling the data and processing them in small batches. After a fixed amount of training on each task, however, we allowed no further training on that task’s dataset.

We constructed the set of tasks from the problem of classifying hand-written digits from the Mixed National Institute of Science and Technology (MNIST) (22) dataset, according to a scheme previously used in the continual-learning literature (23, 24). For each task, we generated a fixed, random permutation by which the input pixels of all images would be shuffled. Each task was thus of equal difficulty to each other, but would require a different solution.

Training on this sequence of tasks with plain stochastic gradient descent (SGD) incurs catastrophic forgetting, as demonstrated in Fig. 3A. The blue curves show performance on the testing sets of two different tasks. At the point at which the training regime switches from training on the first task (A) to training on the second one (B), the performance for task B falls rapidly, whereas for task A it climbs steeply. The forgetting of task A compounds further with more training time and the addition of subsequent tasks. This problem cannot be countered by regularizing the network with a fixed quadratic constraint for each weight (green curves, L2 regularization): here, the performance in task A degrades much less severely, but task B cannot be learned properly as the constraint protects all weights equally, leaving little spare capacity for learning on B. However, when we use EWC, and thus take into account how important each weight is to task A, the network can learn task B well without forgetting task A (red curves). This is exactly the behavior described diagrammatically in Fig. 1.

Previous attempts to solve the continual-learning problem for deep neural networks have relied upon careful choice of network hyperparameters, together with other standard regularization methods, to mitigate catastrophic forgetting. However, on this task, they have achieved reasonable results only up to two random permutations (23, 24). Using a similar cross-validated hyperparameter search to that in ref. 24, we compared traditional dropout regularzation to EWC. We find that stochastic gradient descent with dropout regularization alone is limited and that it does not scale to more tasks (Fig. 3B). In contrast, EWC allows a large number of tasks to be learned in sequence, with only modest growth in the error rates.

Given that EWC allows the network to effectively squeeze in more functionality into a network with fixed capacity, we might ask whether it allocates completely separate parts of the network for each task or whether capacity is used in a more efficient fashion by sharing representations. To assess this, we determined whether each task depends on the same sets of weights, by measuring the overlap between pairs of tasks’ respective Fisher information matrices (Fisher Overlap). A small overlap means that the two tasks depend on different sets of weights (i.e., EWC subdivides the network’s weights for different tasks); a large overlap indicates that weights are being used for both of the two tasks (i.e., EWC enables sharing of representations). Fig. 3C shows the overlap as a function of depth. As a simple control, when a network is trained on two tasks that are very similar to each other (two versions of MNIST where only a few pixels are permuted), the tasks depend on similar sets of weights throughout the whole network (gray dashed curve). When then the two tasks are more dissimilar from each other, the network begins to allocate separate weights for the two tasks (black dashed line). Nevertheless, even for the large permutations, the layers of the network closer to the output are indeed being reused for both tasks. This reflects the fact that the permutations make the input domain very different, but the output domain (i.e., the class labels) is shared.

EWC Allows Continual Learning in a Reinforcement Learning Context.

We next tested whether EWC could support continual learning in the far more demanding reinforcement learning (RL) domain. In RL, agents dynamically interact with the environment to develop a policy that maximizes cumulative future reward. We asked whether Deep Q Networks (DQNs)—an architecture that has achieved impressive successes in such challenging RL settings (25)—could be harnessed with EWC to successfully support continual learning in the classic Atari 2600 task set (26). Specifically, each experiment consisted of 10 games chosen randomly from those that are played at human level or above by DQN. At training time, the agent was exposed to experiences from each game for extended periods of time. The order of presentation of the games was randomized and allowed for returning to the same games several times. At regular intervals we would also test the agent’s score on each of the 10 games, without allowing the agent to train on them (Fig. 4A).

Notably, previous reinforcement learning approaches to continual learning have relied either on adding capacity to the network (27, 28) or on learning each task in separate networks, which are then used to train a single network that can play all games (9, 10). In contrast, the EWC approach presented here makes use of a single network with fixed resources (i.e., network capacity) and has minimal computational overhead.

In addition to using EWC to protect previously acquired knowledge, we used the RL domain to address a broader set of requirements that are needed for successful continual-learning systems: In particular, higher-level mechanisms are needed to infer which task is currently being performed, detect and incorporate novel tasks as they are encountered, and allow for rapid and flexible switching between tasks (29). In the primate brain, the prefrontal cortex is widely viewed as supporting these capabilities by sustaining neural representations of task context that exert top–down gating influences on sensory processing, working memory, and action selection (30–33).

Inspired by this evidence, we augmented the DQN agents with extra functionality to handle switching task contexts. Knowledge of which task is being performed is required for the EWC algorithm as it informs which quadratic constraints are currently active and also which quadratic constraint to update when the task context changes. To infer the task context, we implemented an online clustering algorithm that is trained without supervision.
and is based on the forget-me-not (FMN) process (34) (see Materials and Methods for more details). We also allowed the DQN agents to maintain separate short-term memory buffers for each inferred task. These allow action values for each task to be learned off-policy, using an experience replay mechanism (25).

As such, the overall system has memory on two timescales: Over short timescales, the experience replay mechanism allows learning in the DQN to be based on the interleaved and uncorrelated experiences (25). At longer timescales, know-how across tasks is consolidated by using EWC. Finally, we allowed a small number of network parameters to be game specific. In particular, we allowed each layer of the network to have biases and per-element multiplicative gains that were specific to each game.

We compare the performance of agents that use EWC (red) with ones that do not (blue) over sets of 10 games in Fig. 4. We measure the performance as the total human-normalized score across all 10 games; the score on each game is clipped to 1 such that the total maximum score is 10 (at least at human level on all games) and 0 means the agent is as good as a random agent. If we rely on plain gradient descent methods as in ref. 25, the agent never learns to play more than one game and the harm inflicted by forgetting the old games means that the total human-normalized score remains below one. By using EWC, however, the agents do indeed learn to play multiple games. As a control, we also considered the benefit to the agent if we explicitly provided the agent with the true task label (Fig. 4B, brown), rather than relying on the learned task recognition through the FMN algorithm (Fig. 4B, red). The improvement here was only modest.

Whereas augmenting the DQN agent with EWC allows it to learn many games in sequence without suffering from catastrophic forgetting, it does not reach the score that would have been obtained by training 10 separate DQNs (Fig. S3). One possible reason for this is that we consolidated weights for each game based on a tractable approximation of parameter uncertainty, the Fisher information. We therefore sought to test the quality of our estimates empirically. To do so, we trained an agent on a single game and measured how perturbing the network parameters affected the agent’s score. Regardless of which game the agent was trained on, we observed the same patterns, shown in Fig. 4C. First, the agent was always more robust to parameter perturbations shaped by the inverse of the diagonal of the Fisher information (blue), as opposed to uniform perturbations (black). This validates that the diagonal of the Fisher information is a good estimate of how important a parameter is. Within our approximation, perturbing in the null space should have no effect on performance. Empirically, however, we observe that perturbing in this space (orange) has the same effect as perturbing in the inverse Fisher space. This suggests that we are overconfident about certain parameters being unimportant: It is therefore likely that the chief limitation of the current implementation is that it underestimates parameter uncertainty.

Discussion

We present an algorithm, EWC, that allows knowledge of previous tasks to be protected during new learning, thereby avoiding catastrophic forgetting. It does so by selectively decreasing the plasticity of weights and thus has certain parallels with neurobiological models of synaptic consolidation (15, 16). We implement EWC as a soft, quadratic constraint whereby each weight is pulled back toward its old values by an amount proportional to its importance for performance on previously learned tasks. In analytically tractable settings, we demonstrate that EWC can protect network weights from interference and thus increase the fraction of memories retained over plain gradient descent. To the extent that tasks share structure, networks trained with EWC reuse shared components of the network. We further show that EWC can be effectively combined with deep neural networks to support continual learning in challenging reinforcement learning scenarios, such as Atari 2600 games.

The EWC algorithm can be grounded in Bayesian approaches to learning. Formally, when there is a new task to be learned, the network parameters are tempered by a prior which is the posterior distribution on the parameters given data from the previous task(s). This enables fast learning rates on parameters that are poorly constrained by the previous tasks and slow learning rates for those that are crucial.

There has been previous work (35, 36) using a quadratic penalty to approximate old parts of the dataset, but these applications have been limited to small models. Specifically, ref. 35 used random inputs to compute a quadratic approximation to the energy surface. Their approach is slow, as it requires recomputing the curvature at each sample. The ELLA algorithm described in ref. 36 requires computing and inverting matrices with a dimensionality equal to the number of parameters being optimized; therefore it has been mainly applied to linear and logistic regressions. In contrast, EWC has a run time that is linear in both the number of parameters and the number of training examples. We could achieve this low computational complexity only by using a crude Laplace approximation to the true the posterior distribution of the parameters. Despite its low computational cost and empirical successes—even in the setting of challenging RL domains—our use of a point estimate of the
posterior’s variance (as in a Laplace approximation) does constitute a significant weakness (Fig. 4C). Our initial explorations suggest that one might improve on this local estimate by using Bayesian neural networks (37).

Whereas this paper has primarily focused on building an algorithm inspired by neurobiological observations and theories (15, 16), it is also instructive to consider whether the algorithm’s successes can feed back into our understanding of the brain. In particular, we see considerable parallels between EWC and two computational theories of synaptic plasticity.

Cascade models of synaptic plasticity (15, 16) construct dynamical models of synaptic states to understand the trade-off between plasticity and memory retention. Cascade models have important differences from our approach. In particular, they aim to extend memory lifetimes for systems in steady state (i.e., the limit of observing an infinite number of stimuli). As such, they allow for synapses to become more or less plastic and model the process of both retaining and forgetting memories. In contrast, we tackle the simpler problem of protecting the network from interference when starting from an empty network. In fact in EWC weights can only become more constrained (i.e., less plastic) with time and thus we can model only memory retention rather than forgetting. Therefore when the number of random patterns observed exceeds the capacity of the network and steady state is reached, EWC starts to perform even worse than plain gradient descent (Fig. 2, Bottom). Further, the EWC model—like standard Hopfield networks (38)—is prone to the phenomenon of blackout catastrophe when network capacity is saturated, resulting in the inability to retrieve any previous memories or store new experiences. Notably, we did not observe these limitations under the more realistic conditions for which EWC was designed—likely because the network was operating well under capacity in these regimes.

Despite these key differences, EWC and cascade share the basic algorithmic feature that memory lifetimes are extended by modulating the plasticity of synapses. Whereas prior work on cascade models (15, 16) has tied the metaplastic state to patterns of potentiation and depression events—i.e., synaptic-level measures—our approach focuses on the computational principles that determine the degree to which each synapse might be consolidated. It may be possible to distinguish these models experimentally, because the plasticity of a synapse depends on the rate of potentiation events in the cascade model, but on task relevance in EWC.

In this respect, the perspective we offer here aligns with a recent proposal that each synapse stores not only its current weight, but also an implicit representation of its uncertainty about that weight (39). This idea is grounded in observations that postsynaptic potentials are highly variable in amplitude (suggestive of sampling from the weight posterior during computation) and those synapses that are more variable are more amenable to potentiation or depression (suggestive of updating the weight posterior). Although we do not explore the computational benefits of sampling from a posterior here, our work aligns with the notion that weight uncertainty should inform learning rates. We take this one step further, to emphasize that consolidating the high precision weights enables continual learning over long timescales. With EWC, three values have to be stored for each synapse: the weight itself, its variance, and its mean. Interestingly, synapses in the brain also carry more than one piece of information. For example, the state of the short-term plasticity could carry information on the variance (39, 40). The weight for the early phase of plasticity (41) could encode the current synaptic strength, whereas the weight associated with the late phase of plasticity or the consolidated phase could encode the mean weight.

The ability to learn tasks in succession without forgetting is a core component of biological and artificial intelligence. In this work we show that an algorithm that supports continual learning—which takes inspiration from neurobiological models of synaptic consolidation—can be combined with deep neural networks to achieve successful performance in a range of challenging domains. In doing so, we demonstrate that current neurobiological theories concerning synaptic consolidation do indeed scale to large-scale learning systems. This provides prima facie evidence that these principles may be fundamental aspects of learning and memory in the brain.

Materials and Methods

Full methods for all simulations can be found in Random Patterns, MNIST Experiments, and Atari Experiments. Hyperparameters for the MNIST experiment are described in Table S1. For the Atari 2600 experiments, we used an agent very similar to that described in ref. 42. The only differences are that we used (i) a network with more parameters, (ii) a smaller transition table,
(iii) task-specific bias and gains at each layer, (iv) the full action set in Atari, (v) a task-recognition model, and (vi) the EWC penalty. Full details of hyper-parameters are described in Table S2. Here we briefly describe the two most important modifications to the agent: the task-recognition module and the implementation of the EWC penalty.

We treat the task context as the latent variable of a hidden Markov model. Each task is therefore associated to an underlying generative model of the observations. The main distinguishing feature of our approach is that we allow for the addition of new generative models if they explain recent data better than the existing pool of models by using a training procedure inspired by the FNN process in ref. 33 (see Atari Experiments for full description). To apply EWC, we compute the Fisher information matrix at each task switch. For each task, a penalty is added with the anchor point given by the current value of the parameters and with weights given by the Fisher information matrix times a scaling factor λ that was optimized by hyperparameter search. We added an EWC penalty only to games that had experienced at least 20 million frames.
