Predicting perturbation patterns from the topology of biological networks

Marc Santolini,a,b,c,d and Albert-László Barabási,a,b,c,d,e,1

High-throughput technologies, offering an unprecedented wealth of quantitative data underlying the makeup of living systems, are changing biology. Notably, the systematic mapping of the relationships between biochemical entities has fueled the rapid development of network biology, offering a suitable framework to describe disease phenotypes and predict potential drug targets. However, our ability to develop accurate dynamical models remains limited, due in part to the limited knowledge of the kinetic parameters underlying these interactions. Here, we explore the degree to which we can make reasonably accurate predictions in the absence of the kinetic parameters. We find that simple dynamically agnostic models are sufficient to recover the strength and sign of the biochemical perturbation patterns observed in 87 biological models for which the underlying kinetics are known. Surprisingly, a simple distance-based model achieves 65% accuracy. We show that this predictive power is robust to topological and kinetic parameter perturbations, and we identify key network properties that can increase up to 80% the recovery rate of the true perturbation patterns. We validate our approach using experimental data on the chemotactic pathway in bacteria, finding that a network model of perturbation spreading predicts with ~80% accuracy the directionality of gene expression and phenotype changes in knock-out and overproduction experiments. These findings show that the steady advances in mapping out the topology of biochemical interaction networks opens avenues for accurate perturbation spread modeling, with direct implications for medicine and drug development.

In the past decade we have witnessed great progress toward the systematic and comprehensive mapping of the physical interactions between the biochemical entities that make up the cells that together represent the human interactome (1–3). These advances have fueled the rapid development of network biology as a suitable framework to describe and understand cellular processes and how their collective perturbations affect disease states (1, 4–8). The underlying data fueling these advances include but are not restricted to protein–protein interactions, gene regulation, metabolic reactions, and kinase-substrate interactions. Through the aggregation of systematic and literature-derived interactions from multiple resources, the human interactome covers today 170,000+ physical interactions between ~14,000 biochemical entities (7). Complementing this wealth of the interaction data, a massive amount of data are routinely generated at the miRNA, mRNA, and protein level through large-scale measurements of their abundance in various cell types, organisms, and conditions populating databases such as Gene Expression Omnibus (9).

From the knowledge of the interactome, the goal of network biology is to quantify and predict the spread of perturbations across the subcellular network. Such perturbation patterns are of crucial importance for network medicine, helping us understand the differential expression patterns observed in disease states. Moreover, being able to prioritize the effect of biological perturbations in silico is key given the cost, time, and difficulty to obtain such data through perturbation experiments, especially for human subjects. However, while the coverage of the interactome is increasing steadily, network biology continues to lack a general quantitative dynamical framework for such predictive modeling. This is in part due to the rarity of large-scale measurements of the kinetic parameters necessary to populate the kinetic models of all pathways (10, 11). Moreover, the degree of reproducibility of the measured kinetic parameters varies wildly between in vitro and in vivo experiments (12). Other approaches pertaining to the global fitting of kinetic parameters (13, 14) by optimizing the model agreement to available data often yield large parameter uncertainties (15, 16). To bypass the need of a full knowledge of kinetic parameters, other studies have investigated the interplay between generic dynamical models and topological structure in the context of biological networks (17, 18). These studies have focused on retrieving global perturbation statistical properties from microscopic models (17), or retrieving the most probable underlying dynamical model from perturbation statistics (18). However, such universal insights are of limited predicting power when confronted with small-size biological models with heterogeneous dynamics. Topological models have been proposed to study perturbation spread in biological networks, such as Boolean networks (19) or normalized-Hill models (NHMs) (20). However, such studies are usually limited to a few well-described, small networks, not offering a comprehensive picture of the accuracy of topological models when applied to a large diversity of real-world biological networks.

Significance

The development of high-throughput technologies has allowed mapping a significant proportion of interactions between biochemical entities in the cell. However, it is unclear how much information is lost given the lack of measurements on the kinetic parameters governing the dynamics of these interactions. Using biochemical networks with experimentally measured kinetic parameters, we show that a knowledge of the network topology offers 65–80% accuracy in predicting the impact of perturbation patterns. In other words, we can use the increasingly accurate topological models to approximate perturbation patterns, bypassing expensive kinetic constant measurement. These results could open new avenues in modeling drug action and in identifying drug targets relying on the human interactome only.

While we continue to lack large-scale measurements of kinetic parameters, the literature has flourished with detailed biochemical models of smaller scale. This is indicated by the growing body of databases dedicated to the storage of biological models (21). For example, the repository of computational models of biological processes BioModels has seen a steady growth of its content over the last decade and currently hosts over 1,200 models derived directly from the literature (22). These models contain detailed information on the particular biological components, their interactions, and the differential equations describing their dynamics.

The fine-grained level of detail these biochemical models offer opens an avenue to explore what level of description is necessary (and sufficient) to reproduce the perturbation patterns characterizing biological networks. In particular, previous work has shown that some perturbation patterns are robust to significant changes in kinetic parameters (23, 24). Indeed, only a small subset of model parameters affect the overall dynamics, a property known as “sloppiness” (25). Accordingly, a simplified dynamical model containing only a few parameters has been found to accurately predict perturbation patterns obtained with a full biochemical model in the case of the beta-adrenergic pathway (20). While these studies focus on perturbations around a given steady state, their results have been extended to the full dynamical landscape of biological networks (26). Using random kinetic models, Huang et al. (26) have shown in the cases of toggle-switch-like motifs and a 22-node biological network that the stable states converge to experimentally observed gene state clusters even when the parameters are strongly perturbed, suggesting that the dynamics is determined mainly by the circuit topology, not by detailed kinetic parameters.

Here we develop DYNAMics-Agnostic Network MOdels (DYNAMO), an ensemble of perturbation propagation models that rely on the network topology alone, and investigate the extent to which the relative magnitude of biological perturbations can be retrieved when we lack knowledge of the kinetic parameters and the details characterizing the dynamics of the underlying biochemical process. Using an “onion-peeling” strategy across a variety of detailed biochemical models, we systematically quantify the loss of accuracy of the predicted perturbation patterns when we successively remove information on the specifics of the dynamics. We show that an accurate knowledge of the network topology captures on average 65% of the influence patterns of the full biochemical model. We then identify global network features that guarantee higher accuracies, reaching up to 80% predictive power. Finally, the underlying modeling framework and its level of accuracy are validated using perturbation experiments in the chemotaxis network in bacteria.

Results

Modeling Influence Patterns in Biological Networks. When the concentration of a biological species is perturbed, the perturbation can spread along physical interactions and reactions, reaching other parts of the network (Fig. 1A). A purely topological approach predicts a uniform spread across the network. First neighbors are affected the most, followed by second neighbors, and so on. In reality, each interaction is governed by a specific dynamical equation with an associated set of parameters, allowing for a precise computation of influence propagation. We must consider the full dynamics to determine the precise direction and the rate at which a perturbation spreads within the network.

Here we investigate the degree to which these dynamical patterns can be retrieved from simple topological features. To that aim, we explore several models of influence propagation with increasing complexity, both in terms of accuracy of representation of the underlying network topology and in terms of dynamical model used (Fig. 1B–E and Methods). We describe network topology in terms of four layers of increasing complexity: (i) undirected network, (ii) directed network, (iii) directed and signed (activating/inhibiting) network, and (iv) directed, signed, and weighted network. To illustrate these layers, consider two interacting species A and B, where an increase in A causes B to increase while a change in B does not affect A. The four layers of complexity successively describe the knowledge that (i) A and B interact (the existence of a link), (ii) A causes a change in B’s concentration (direction of influence), (iii) A causes a positive change in B’s concentration (sign), and (iv) A causes a positive change in B’s concentration of a certain strength (magnitude determined by the link weight parameters, like kinetic constant). All this information can be extracted from the Jacobian matrix of the system (Methods), which qualifies the degree to which a change in A’s concentration causes a change in B’s concentration, and the direction of the change (positive for an increase or negative for a decrease). In this work, the Jacobian matrix is constructed from the underlying systems of dynamical equations characterizing a biological model. The signed Jacobian matrix is then used to reconstruct the underlying weighted topology of the biological models, allowing us to capture topologies of type i to iii. The topology of type iv, built from the full Jacobian matrix, contains the kinetic parameters information and hence corresponds to the full biochemical model. Therefore, from the Jacobian matrix we extract both the topology and perturbation dynamics of the studied models.

Given a network topology (wiring diagram), we wish to predict how the perturbation of a given species propagates over the network and the degree to which it affects all other species. Such perturbation patterns—which we call influence patterns—are usually represented by a sensitivity matrix—a response matrix or correlation matrix in the literature (27)—describing the change in the steady-state value $x_i$ of a node $i$ when the steady-state value $x_j$ of another node $j$ is varied (27, 28):

$$S_{ij} = \frac{dx_i}{dx_j}$$

If the dynamical equations are known, the sensitivity matrix can be analytically derived using a perturbative framework (17, 27) (Methods). In the following we refer to this exact sensitivity matrix as the “(full) biochemical model,” which is the underlying model from which it is computed (Fig. 1B).

We explore three models of decreasing complexity to compute the sensitivity matrix using topological information only (Fig. 1C–E). We refer to them as DYNAMO:

i) We start with a “propagation model” (Fig. 1C) proposed in the context of disease gene prioritization, where “influence” spreads from a set of known seed genes to highlight putative disease genes (29). In our case, perturbed species are seed genes and we want to prioritize the perturbation level of the other species. In this model, the predicted perturbation of a node is proportional to the degree-weighted sum of the perturbations of its neighbors, with a constant input term added for the “source” node being perturbed. This propagation model has been shown to outperform a random walk algorithm in prioritizing disease genes across 1,369 diseases (29).

ii) The “distance model” (Fig. 1D) assumes that the strength of a perturbation is inversely proportional to the network distance between a species and the source of perturbation, that is, the number of interactors it takes for one species to affect the expression of another. Such a model is of great interest since network distance in the interactome is a remarkable predictor of similarity between diseases (7) and drug–disease association (30).

iii) The minimal “first-neighbor” model (Fig. 1E) assumes that the perturbation reaches only the direct neighbors of a perturbed node. Such direct neighbor influence, also called the “local impact hypothesis” (31), has proven fruitful for disease gene prediction (32) and is at the core of the minimum dominating set (MDS) controllability approach, where a minimal group of nodes is identified such that all other nodes in the network have a direct interaction with MDS node and can
therefore be suitably “controlled” or influenced. Applied to the protein–protein interactome, the resulting MDS proteins were shown to be more essential and disease-related than non-MDS proteins (33). As perturbations first impact the first neighbors of the perturbed nodes, the first-neighbor model is the most minimal approximation we explore.

In the following we apply these models to a diverse set of well-characterized biochemical models.

**Topological Models Accurately Predict Influence Patterns in Biological Models.** To test the validity of our findings on a large and diverse set of biological networks, we start from the BioModels database, a repository of curated biological, dynamical models (Methods). Biological models from this database are deposited in a standard format allowing us to extract the underlying set of differential equations describing their dynamics using libSBML (34) (Fig. 2A). From the dynamical equations, we derive the influence networks by linking a species $i$ to a species $j$ if a permanent change in the concentration of $i$ directly affects the steady-state concentration of species $j$. To do so, we first compute the Jacobian matrix of the system. Writing the dynamical equations as $\dot{x}_i = f_i(x_1, \ldots, x_N)$, where $N$ describes the number of species in the model and $x_i$ is the concentration of species $i$, the Jacobian is $J_{ij} = \frac{\partial f_i}{\partial x_j}(x^*)$, where $x^*$ is the steady state of the system (Fig. 2B). The adjacency matrix $A$ of the network is computed as $A = \text{sign}(J^T(x^*))$, where $J^T$ denotes the transpose of the Jacobian of the system and the sign function applies element-wise (Methods and Fig. 2C). In this framework, links with negative weights correspond to inhibitory interactions while positive weights denote activating interactions. This approach is reminiscent of inference networks (35), with link directions systematically reversed.
We implemented 87 models from BioModels (Dataset S1 and ref. 22), selected with the criterion that the largest connected component contains at least 10 species. For each model, biochemical and DYNAMO sensitivities are computed as follows (see Methods for additional details). For biochemical models, the sensitivity matrix is obtained via (17, 27)

$$S = (I - J)^{-1}D(\frac{1}{(I - J)^{-1}}),$$  \[2\]

where $I$ is the identity matrix and $J$ denotes the Jacobian matrix of the system around steady state (Methods). For network models, we start from spreading models $i-iii$ from the DYNAMO model family (Fig. 1 C-E). To compute the influence of a node on the other nodes in the network, we start by assigning all nodes a weight zero. Given a perturbation in node $i$ (weight 1), the influence propagates to other nodes $j$ in the network, changing their weights according to various proposed models. The matrix of influence for any pair $(i, j)$ constitutes the sensitivity matrix. The models are as follows:

i) Propagation: We extend the PRINCE methodology to the case of directed and signed networks (29) (Methods). Noting with $W$ the adjacency matrix, we define the diagonal matrix $D_1$ such that $D_1(i, i)$ is the sum of the absolute values of row $i$ of $W$ and the matrix $D_2$ such that $D_2(i, i)$ is the sum of the absolute values of column $i$ of $W$. We then compute the normalized propagation weights $W' = D_0^{-1/2}WD_2^{1/2}$ and the sensitivity matrix as

$$S = (1 - \alpha)(I - \alpha W')^{-1},$$  \[3\]

where $\alpha = 0.9$ is a parameter characterizing the propagation strength. This sensitivity matrix corresponds to the spread of a perturbation of weight 1 to the rest of the network.
ii) Distance: We assume that influence propagates to all nodes in the same connected component as node \( i \). In the directed case, propagation is limited to outgoing links. Weights decrease with distance \( d \) as \( 1/(1+d) \). We note that there is no “signed” case for the distance model. Indeed, there are in theory several shortest paths of the same length joining any two nodes, and it is unclear which one to choose and how to carry the edge signs from the source to the target.

iii) First neighbors: We assume that influence propagates only to the direct neighbors of \( i \), setting their weights to 1 (or \(-1\) for a negative interaction). For directed networks, only outgoing links are considered.

The sensitivity matrices are compared with the one predicted from the full biochemical model using Spearman correlation (Fig. 2D and Methods). This nonparametric measure compares the rank of the sensitivities, not their raw values, thus assessing if the relative strength of perturbations is conserved across models. We use the absolute value of the sensitivities as we focus on recovering the strength of perturbations, not their sign. Fig. 2E summarizes the obtained correlations averaged over all 87 biochemical models (see SI Appendix, Fig. S1 for full distributions), documenting a gradual decrease of the accuracy with the decreasing complexity of the network models. We find that the propagation model, which relies on topological information only, achieves 66% of accuracy (i.e., a Spearman correlation of \( \rho = 0.66 \)) in predicting the influence patterns when the network includes direction and sign of the links. This is only slightly better than in the unsigned case, though not significantly (65%, \( P = 0.4 \) under Student test), but a dramatic improvement over the undirected case (40%, \( P = 5.1 \times 10^{-13} \)), indicating that capturing the direction of flow is essential for predictive accuracy. Interestingly, the simpler distance model on a directed network shows accuracy comparable to that of the best propagation model on a directed signed network (63%). Again, the accuracy greatly decreases in the undirected case to a level similar to the undirected propagation model (36%). Finally, simple first-neighbors models achieve up to \( \sim 27\% \) accuracy, a value close to but higher than the random expectation (Fig. 2E, dashed red line).

Next we explore whether the signed DYNAMO models can correctly predict the signs of the perturbations. Such signs indicate whether the increase in a species concentration causes another species to be up- or down-regulated. This is important as many measurements report sets of down- or up-regulated genes. We therefore compute the proportion of accuracy of sign predictions using the signed propagation and first-neighbor models (Fig. 2F). The results show a similar trend with improvement over the influence strength case, with 78% accuracy (\( P < 1 \times 10^{-16} \)) for the propagation model and 33% (\( P = 1.7 \times 10^{-5} \)) for the first-neighbors model.

Overall, we show that topology accounts for two-thirds of the accuracy budget of dynamical models when predicting perturbation patterns. In particular, we find that the simple distance-based model has performance similar to that of the top-performing propagation model.

**Robustness to Network Incompleteness.** While Fig. 2F confirms the importance of topology in retrieving biochemical influence patterns, it is unclear to what extent the results hold if the underlying interactome is incomplete. Indeed, high-throughput methods cover less than 20% of all potential pairwise protein interactions in the human cell (7). Despite the gradually increasing coverage (1, 36), we can expect to deal with incomplete models for many years to come. This prompts us to address the robustness of our approach to link removal. Since all approaches inherently rely on the Jacobian matrix of the system, removing a nonzero entry is equivalent to removing a link. We show in Fig. 2G the average accuracy of the DYNAMO models in retrieving the original biochemical model sensitivities when removing an increasing proportion of links (i.e., an increasing proportion of entries from the original Jacobian matrix). We observe two different behaviors. For directed models the accuracy decreases linearly, while for undirected models it has a concave shape, decreasing slowly initially then more rapidly with additional link removal. This can be understood by realizing that many models have a substantial fraction of reversible equations, modeled as two links of opposite direction between two nodes. In the undirected case, removing one of those two links does not change the network, making these models therefore more robust to link removal. Moreover, we find that at 50% incompleteness the propagation and biochemical models have similar accuracies, with the biochemical model still slightly better than the propagation one (45% vs. 39%). This demonstrates that with the current level of incompleteness of biochemical networks topological models are competitive with more complex “kinetics-aware” models.

**Network Features Underlying Accurate Influence Prediction.** Given the differences in size and scope across the 87 biological models (Dataset S1), next we investigate what network characteristics contribute to higher prediction accuracy. For this we measured the correlation between various quantities and the directed signed propagation model accuracy across 87 biological models (Fig. 2H). The gray area specifies the 95% confidence interval. We find that the model size has no effect on accuracy, while the dynamics does: The presence of very high Jacobian values, corresponding to fast reactions, leads to smaller accuracies. This stems from the fact that such outliers in the Jacobian matrix can break the link between the other links and lead to faster propagation across selected links in the biochemical model, a feature that cannot be captured by the network topology alone. We also find that the proportion of reversible equations negatively impacts the accuracy. Indeed, directedness does not offer an advantage for network models for BioModels dominated by reversible equations, and the directed propagation model closes the gap with the less-accurate undirected model. This result is supported by the finding that higher accuracies can be reached for networks that can be decomposed into a large number of strongly connected components (SCCs), that is, subgraphs for which every node is reachable from every other node. When filtering out BioModels with only one SCC, we observe significant improvement of the DYNAMO accuracies, reaching to \( \sim 80\% \) accuracy (SI Appendix, Fig. S3). We show in SI Appendix, Fig. S4 two example BioModels with respectively \( n = 1 \) and \( n = 5 \) SCCs. The network with one SCC is dense and poorly modular, while the one with five SCCs is sparser and displays chain-like structures. Supporting such structures, we find higher accuracies for networks that do not display clear hubs (low average degree, eigenvector centrality, and proportion of structural holes) and are sparse (low link density). Finally, since the link weight plays a role through the Jacobian, we would expect that link betweenness centrality should similarly matter, but we find no significant correlation. Overall, we find that topological models reach up to 80% accuracy for biological models with certain network characteristics pertaining to sparsity and modularity.

**Comparison with an NHM.** While our DYNAMO framework encompasses a broad range of topological models, it does not include any combinatorial information and we do not model how entities combine when influencing a node—we consider these combinations to be “OR gates” (i.e., additive functions). Here we compare our simplified DYNAMO models to the kinetic-agnostic Boolean-like NHM (Methods) proposed by ref. 20 that encapsulates such combinatorial features from the original biochemical model (Fig. 3A). The NHM represents the dynamics by sigmoidal activation or inhibition functions parameterized
The biochemical model was approximated by the NHM, characterizing the interactions between 25 species via 33 links. The full biochemical model (37) contains 87 parameters, involved in cardiac hypertrophy and heart failure (Fig. 3B). The full biochemical model (37) was refined to reproduce key quantitative time-course behaviors, as described in ref. 20. (B) Beta-adrenergic signaling network (37). The full biochemical model contains 87 parameters. Reproduced from ref. 37. (C) Same as Fig. 2E. (D) Robustness of the Spearman correlation measure for the beta adrenergic pathway under parameter perturbation (Methods). We show the average correlation between any two perturbed biochemical sensitivity matrices generated (black bars), or the average correlation between each network model and the perturbed biochemical sensitivity matrices (other bars). Error bars show SE. Interestingly, we see no difference between a typical perturbed biochemical model and a network model.

We then explore the robustness of these results to random variations in the biochemical parameters (Methods and Fig. 3D). For this we generate perturbed biochemical models by multiplying all parameters by a factor randomly chosen between ½ and 2. The resulting sensitivity matrices are then used as ground truth biochemical model to compare with the DYNAMO models. We observe that the accuracy of the network models is mostly unchanged when comparing to the perturbed biochemical models (Fig. 3D). However, when comparing the perturbed biochemical model sensitivities with one another, we observe an average accuracy of ~80%, similar to that of the best network models (NHM, propagation, and distance models). This indicates that biochemical models with poorly measured kinetic parameters (up to twofold variation) are as accurate as topological models. This exhibits the utility of such simple topological models in the context where obtaining precise kinetic information would require important experimental investment.

**Topology Predicts Physiological and Phenotypic Perturbations.** While perturbation patterns are of general interest for assessing the quality of our models, testing the true value of the network topology-based modeling framework needs experimental validation. To test the accuracy of the DYNAMO models against experimental observations, we focused on the chemotaxis network in bacteria (Fig. 4A) for which experimental data are available (38) (Methods). This model is part of the BioModels database (22), and the DYNAMO models capture its dynamics with a 90% accuracy (Fig. 4B). The experimental dataset consists of knockouts and overexpression assays of six genes of the chemotaxis network.
their combinations, followed by observation of the change in expression of other genes from the network. In addition, the experiments also report changes in bias, a phenotypic quantity determined by the ratio of multiple biochemical species concentrations and capturing the exploratory behavior during chemotaxis (Methods and Fig. 4C). In Fig. 4D and E we compare the experimental observations (left columns) to the predictions from the propagation model on the signed directed network (right columns) under several assays. We focus on the accuracy in retrieving the correct sign of the observed perturbations. We observe that the network model predicts the observed sign of the perturbations in 86% of the cases for gene expression changes (13 out of 15 cases, \( P = 4.9e-4 \) under binomial test, Fig. 4D). Moreover, it predicts phenotypic changes with 75% accuracy (9 out of 12 cases, \( P = 0.019 \), Fig. 4E), demonstrating the value of topological models in predicting physiologically relevant biological outcomes. Taken together, these results demonstrate that the precision holds when using data from experimental perturbations.

**Discussion**

While the coverage of the physical interactions underlying biological networks has increased considerably in the past decade, we continue to lack accurate and comprehensive data on the kinetic parameters determining the dynamics of each individual process. We must therefore evaluate the predictive potential of purely topological models, quantifying their ability to unlock quantitative insights on physiologically relevant processes. In this work, we proposed a systematic DYNAMO framework to measure the loss in predictive power when we lack the kinetic parameters determining the dynamics of each individual process. We concentrated on the parameters characterizing the spread of perturbations of selected biochemical species, and its impact on all other species in the network. Such patterns are of direct interest as we seek to understand changes in gene expression patterns induced by disease-causing mutations. We used detailed dynamical biochemical models derived from the literature to estimate the accuracy of
the topological models in retrieving the perturbation patterns characterizing the full dynamics. Interestingly, we find that a propagation model on a topology that captures the direction and sign of the interactions can account for ~65% of the full perturbation patterns across all models, an accuracy that can reach 80% for models with certain network characteristics. Furthermore, this model shows only mild improvement over a simpler distance-based model on a directed network. This is important since network distance in the interactome has been used extensively to predict disease similarity between disease genes (7) and drug-disease association between a set of drug targets and disease genes (30). We also find that a simpler first-neighbor model or complex models that lack directionality, though offering smaller accuracy, still carry predictive potential compared with a random reference frame. Moreover, the beta-adrenergic example demonstrated that the best DYNAMO topological models can be as informative as slightly perturbed biochemical models where kinetic parameters would carry measurement noise. They also offer an accuracy comparable to that of models with more complex nonlinear dynamics, key parameters fit, and multiplicative input functions.

A usual concern raised about the predictive power of biochemical networks is that the interactome is far from complete. We therefore addressed the robustness of our approach to link removal, finding that the DYNAMO models are in general more robust than the biochemical model to link removal, and that the propagation model has accuracy comparable to that of the biochemical model at 50% incompleteness. Therefore, we find that the kinetic-agnostic DYNAMO models are as predictive as the full biochemical models in the context of incomplete interactome.

We also explored which network characteristics offer greater accuracy for the DYNAMO framework. This is important as it allows one to know before any kinetic parameters have been measured whether that information would lead to a drastic improvement over a topological model. The analysis indicates that networks that can be decoupled into many strong connected components (i.e., many chain-like structures) and are in general sparse (low degree nodes and link density) lead to higher DYNAMO accuracies.

Finally, exploring the topological models’ ability to predict observed outcomes from experimental perturbations in the chemotaxis pathway, we find a 75–85% accuracy, a result in agreement with the previous accuracies computed for the full perturbation patterns.

This work has important implications for our understanding of the role of the different modeling frameworks currently in use in network biology and medicine. The ability to extract information on the spread of perturbations from an accurate knowledge of the topology of biological networks will be of great value for drug development. In particular, the linearity of the equation used to predict perturbation patterns in the propagation model makes it straightforward to explore any combination of perturbations, therefore paving the way for a better understanding of drug combinations and improved therapies. Overall, our findings indicate that the lack of large-scale measurements of the kinetic parameters may not prevent network biology from offering quantitative and accurate predictions on perturbation processes. On the contrary, focusing on topology appears well-justified as it holds the largest share of the descriptive power in this endeavor.

**Methods**

**BioModels Database.** Models from the BioModels ftp website (ftp://ftp.ebi.ac.uk/pub/databases/biomodels) were used. We used the BioModels Database-r30_pub-sbml files dataset (ftp://ftp.ebi.ac.uk/pub/databases/biomodels/releases/2016-05-10). SBML files were processed using libsbml matlab library to extract the dynamical equations (34).

**Derivation of the Influence Network.** We converted the reactions from BioModels SBML files to reaction networks using libSBML (34). We first extracted the differential equations describing the dynamical models in the form \( x_i = f_i(x_0, x_0, \ldots) \), where \( N \) describes the number of species in the model and \( x\_i \) is the concentration of species \( i \). These equations are in turn converted to an “influence network” where a link from species \( i/j \) is created if \( i/j \) is in the differential equation describing the evolution of \( j \) (i.e., if \( \partial f_i/\partial x_j \) is not identically zero). The sign of the link is the sign of \( \partial f_i/\partial x_j(x*) \), where \( x* \) is the steady-state vector of species concentration. In other words, the influence network is sign(\( f_i(x*) \)) where \( f^T \) is the transpose of the Jacobian describing the system. Models were integrated using the ode23tb function from MATLAB R2016a and the Jacobian was computed using finite difference method with step size \( 1 \times 10^{-3} \).

**Computation of Biochemical Sensitivities.** The biochemical sensitivities are computed following refs. 17 and 27. Writing the dynamical equations as a weighted sum over all network paths between a perturbed node and an initial perturbation. A perturbation spreads to neighboring nodes with a probability multiplied by the sign of this element. Accordingly, sensitivities can be thought of as a weighted sum over all network paths between a perturbed node and an impacted node, with each path carrying a positive (negative) weight if the path contains an even (odd) number of negative signs. As such, the absolute values of the sensitivities of the directed signed diffusion model are smaller or equal to the sensitivities of the directed diffusion model, ensuring convergence.

Note that in the propagation model the variation of \( a \) changes the diffusion capability. However, we observed no significant change in the influence strength recovery across 87 BioModels when varying \( a \) (SI Appendix, Fig. S2A). Indeed, we are interested in the ranks of the observed sensitivities (the most- vs. the least-perturbed species), which is why we use the non-parametric Spearman rank correlation. We show in the case of the chemotaxis pathway that while the change of \( a \) alters the values predicted by the propagation model (SI Appendix, Fig. S2 B and C), it has no effect on the rank of the model sensitivities (SI Appendix, Fig. S2 D and E), leaving the Spearman correlation almost unchanged (SI Appendix, Fig. S2A).

In the case of the beta-adrenergic pathway, we use the normalized-Hill function system developed in ref. 20. This model includes a simple non-linear dynamics and multiplicative inputs on select cases as informed from the literature. Species interactions were defined with normalized activating or inhibiting Hill functions (\( f_{ah} \) or \( f_{nah} \)) and pathway cross-talk was implemented using logical AND and OR operations: \( f(x) \cdot f(y) + f(x) \cdot f(y) = f(x/y) \), respectively. The normalized activating or inhibiting Hill functions have the form...
