Edited by Krishna K. Niyogi, University of California, Berkeley, CA, and approved September 19, 2019 (received for review June 4, 2019)

In oxygenic photosynthetic organisms, photosystem II (PSII) is a unique membrane protein complex that catalyzes light-driven oxidation of water. PSII undergoes frequent damage due to its demanding photochemistry. It must undergo a repair and reassembly process following photodamage, many facets of which remain unknown. We have discovered a PSII subcomplex that lacks 5 key PSII core reaction center polypeptides: D1, D2, PsbE, PsbF, and PsbI. This pigment-protein complex does contain the PSII core antenna proteins CP47 and CP43, as well as most of their associated low molecular mass subunits, and the assembly factor Psb27. Immunoblotting, mass spectrometry, and ultrafast spectroscopic results support the absence of a functional reaction center in this complex, which we call the “no reaction center” complex (NRC). Analytical ultracentrifugation and clear native PAGE analysis show that NRC is a stable pigment-protein complex and not a mixture of free CP47 and CP43 proteins. NRC appears in higher abundance in cells exposed to high light and impaired protein synthesis, and genetic deletion of PsbO on the PSII luminal side results in an increased NRC population, indicative that NRC forms in response to photodamage as part of the PSII repair process. Our finding challenges the current model of the PSII repair cycle and implies an alternative PSII repair strategy. Formation of this complex may maximize PSII repair economy by preserving intact PSII core antennas in a single complex available for PSII reassembly, minimizing the risk of randomly diluting multiple recycling components in the thylakoid membrane following a photodamage event.

Photosystem II (PSII) is a large pigment–protein complex embedded in the thylakoid membrane of all oxygenic photosynthetic organisms: Cyanobacteria, algae, and plants. PSII plays a central role in energy flow in the biosphere by harnessing sunlight to split water molecules into protons, electrons, and molecular oxygen, ultimately yielding the vital high-energy molecules ATP and NADPH. This conversion of solar energy to chemical energy powers nearly all life on Earth, while simultaneously producing the oxygen we breathe. Crystal structures of functional PSII (1–6) have revealed that the water-splitting reaction is catalyzed by a Mn4CaO5 (Mn) cluster bound to the luminal surface of PSII. D1 and D2, 2 ∼30-kDa transmembrane proteins, form a heterodimer at the center of PSII. They coordinate the primary electron transport chain cofactors and contribute most of the Mn-cluster ligands. D1 and D2 associate with the smaller (<10 kDa) subunits PsbE and PsbF (e- and β-subunits of cytochrome b6f) and PsbI. Together, these 5 proteins comprise the core “reaction center” (RC) complex, the smallest PSII subcomplex capable of light-induced charge separation (7). Surrounding the RC subunits are CP47 and CP43, 2 ∼50-kDa proteins that bind chlorophyll a (Chl a) molecules and serve as antennas, harvesting and funneling light energy toward the RC to drive PSII photochemistry. Around 10 additional low molecular mass (LMM) subunits bind to fully assembled PSII, contributing to the structural and functional optimization of the complex (8). Finally, functional PSII contains several membrane-extrinsic hydrophilic proteins (PsbO, PsbU, PsbV, and PsbQ in cyanobacteria) (9, 10), bound at the luminal surface of the complex, that stabilize the Mn cluster.

PSII undergoes frequent oxidative damage because of the demanding electron-transfer chemistry it performs (11–13). D1, closely followed by D2, is damaged and replaced most frequently of all proteins in the complex (14–18). However, CP47 and CP43 are more long lived (15, 17). This damage leads to partial disassembly of PSII, replacement of each damaged subunit with a new copy, and reassembly of PSII, in an intricate process known as the PSII repair cycle (14, 19, 20) (SI Appendix, Fig. S1). This cycle operates concurrently with de novo PSII synthesis. Synthesis of PSII occurs through stepwise assembly of PSII from component subcomplexes, in which the RC complex is joined with the CP47 precomplex first, followed by addition of the CP43 precomplex, and finally addition of membrane-extrinsic proteins (SI Appendix, Fig. S1). Current understanding is that repair occurs in much the same fashion, with removal of the extrinsic subunits, followed by the CP43 precomplex, replacement of D1 and/or D2 at the RC47 postulated...
level, and reassembly of PSII (14, 19, 20) (SI Appendix, Fig. S1). Many accessory proteins, such as Psb27 and Psb28 (21–25), bind exclusively to particular PSII subcomplexes to aid in a specific aspect of assembly. Despite this working model, our understanding is still evolving. Subcomplexes are low in abundance and transient in nature, and a complete characterization of all is far from complete. The steps that occur following photodamage are particularly uncertain, as repair subcomplexes are typically less amenable to targeted accumulation using PSII mutant strains than are intermediates of de novo assembly.

In this study, we describe the identification of a PSII subcomplex from the cyanobacterium *Synechocystis* sp. PCC 6803 (*Synechocystis* 6803). This subcomplex specifically lacks the 5 RC subunits, and therefore, we refer to it as the “no-RC” (NRC) complex. It accumulates to higher abundance in conditions of elevated PSII damage and impaired protein synthesis, leading us to conclude that the NRC is an intermediate in the repair cycle of PSII. A revised model of the repair steps following PSII photodamage is presented in light of our findings. We propose that NRC formation maximizes the efficiency of PSII repair and minimizes collateral damage to components of PSII that were unharmed following an initial photodamage event.

**Results**

**Isolation of a PSII Subcomplex.** We purified PSII complexes from the His47 and Δ*psbO*-His47 strains of *Synechocystis* 6803 by FPLC using a nickel-affinity column. His47 has a C-terminal His-tag on the CP47 subunit of PSII, and Δ*psbO*-His47 is the same strain with an inser- tional deletion of the *psbO* gene. These complexes were then analyzed by high-resolution clear native acrylamide gel electrophoresis (Fig. 1A). As expected, in the Δ*psbO*-His47 strain, a major band was seen that represents the PSII monomer (PSII-M), whereas no PSII dimer was found as it is not formed in this strain (10, 25). Additionally, a green band just below the monomer was observed that corresponds to the RC47 complex previously observed in the literature (14, 20). In the His47 strain, a major band was seen that represents the PSII dimer (PSII-D), while PSII-M and the RC47 bands were also present. Interestingly, an additional green band of unknown identity was present at a lower molecular weight (MW) than the monomer in each strain. In-gel digestion followed by tandem mass spectrometry (MS) indicated sharply decreased D1, D2, and PsbE content in the lower MW band from both strains compared to PSII-M (Dataset S1), and presence of CP47 and CP43, although other assay methods were needed (see below) for more reliable quantitative information.

To obtain a sufficient quantity for further characterization of the unknown complex, PSII preparations were then subjected to glycerol gradient ultracentrifugation to separate distinct His47–containing complexes (Fig. 1B). Again as expected, in the Δ*psbO*-His47 strain, a major band was seen that represents the PSI monomer (PSII-M), whereas no PSII dimer was found as it is not formed in this strain (10, 25), and in the His47 strain, a major band was seen that represents the PSII dimer (PSII-D) in addition to the monomer band. Consistent with the results in the clear native gel, a lower MW chlorophyll-containing band was observed in each strain. This band was harvested and concentrated. When the purified lower MW band from the Δ*psbO* strain was run next to Δ*psbO*-PSII by clear native gel electrophoresis, it comigrated with the band observed initially (SI Appendix, Fig. S2). Tandem MS was performed after in-solution digestion of the complex from Δ*psbO* cells. The dominant PSI proteins were CP47 and CP43. According to the semiquantitative information derived from such an experiment, levels of D1, D2, PsbE, and PsbF were markedly decreased compared to the corresponding PSI-M (Datasets S2 and S3), consistent with the results from in-gel digestion on the lower MW band described above.

The 77-K absorption spectra of Δ*psbO*-PSII-M and the complex were nearly identical (Fig. 1C), with the exception that a small peak around 540 nm corresponding to pheophytin a (26) was absent in the spectrum of the complex. Pheophytin a is a cofactor in the PSII electron-transfer chain and is coordinated by D1 and D2.

SDS/PAGE analysis showed no band detectable for the core RC proteins D1 and D2 (Fig. 2A). However, it contained the inner antenna subunits CP47 and CP43, as well as Psb27, which binds to CP43 transiently during PSII assembly and repair (21, 22, 27, 28). In functional PSII, Chls a bound to CP47 and CP43 harvest light and transfer excitation energy to Chls a on D1 and D2, where primary PSII photochemistry occurs. A subcomplex containing both antenna proteins but lacking the 2 RC subunits to which they transfer energy was a surprising finding, as such a complex has not been observed previously and does not appear in the current model of the PSI lifecycle (SI Appendix, Fig. S1).

Consistent with SDS/PAGE, immunoblotting analysis (Fig. 2B and C) showed no detectable levels of D1 and D2 in the complex isolated from both the Δ*psbO* and His47 strains. Additionally, PsbE, another member of the PSI RC complex, was also absent (7). Presence of CP43 and CP47 in this complex, however, was confirmed, and the CP47-associated LMM subunit PsbH was detected as well. The MS results that showed severely decreased, but detectable, levels of D1 and D2 in the sample reflect the high sensitivity of the Q-Exactive MS instrument and the inevitability of some impurities remaining in the sample following purification. However, the SDS/PAGE and immunoblot results show that even
The NRC Complex Shows a Major Species at 6.1 S (Svedberg)

...of the PSII-M and NRC samples were determined from 
ultracentrifugation (AUC). Distributions of the Chl-containing 
absolute MW of the intact, native complex, we used analytical 
dissociation products. For MW determination, the sedimentation equilibrium curves were analyzed using a 2-species fit based on the observation of 2 species from the sedimentation velocity experiments. The PSII-M sample showed a major species at 11.6 S (Fig. 3A, peak f), and 3 minor species at 2.9 S, 5.4 S, and 9.0 S. The molecular mass of the major species was estimated as 436 kDa, with a best-fit frictional coefficient ratio of 1.27, comparable to the MW of the PSII monomer determined in a previous study by Zoumi et al. (29), using a similar method. The 3 minor species likely represent dissociation products.

The NRC Complex Lacks a Functional RC. The absence of the RC proteins in the NRC suggests that the complex cannot function as an RC. To test this hypothesis, we used ultrafast time-resolved fluorescence (TRF) measurements on the PSII-M and NRC samples. Both samples were excited at 625 nm, corresponding to a vibronic overtone of the Chl a Qy band, and the Chl a fluorescence decay was monitored (Fig. 4 A and B, shown as pseudocolor 2D plots). The profiles revealed two components with lifetimes of 4.6 ns and 250 ps, respectively. The longer component, with a lifetime of 4.6 ns, was very similar to the fast NRC component, suggesting that both originate from the same species. The lifetime of 4.6 ns closely resembled that obtained for isolated CP47 and CP43 proteins (31), implying that no further excitation energy transfer occurs in the NRC complex, and this component corresponds to intrinsic decay of excited Chl a. Overall, these results demonstrated that excitation energy in PSII-M that was initially localized on Chl a bound to CP47 and CP43, was efficiently transferred to the RC. These PSII-M results closely mimic those obtained for PSII core complexes from the cyanobacterium Thermosynechococcus vulcanus under similar conditions (30). The slower NRC component, however, with a lifetime of 250 ps, was very similar to the fast NRC component, suggesting that both originate from the same species.

**Fig. 2.** Major protein components of NRC. (A) SDS/PAGE analysis of PSII-M and PSII-NRC samples from the ΔΔΔΔHis47 strain, and of PSII-M purified identically from the His47 strain. (B) Immunoblot analysis of PSII-M and PSII-NRC samples from the His47 strain. (C) Immunoblot analysis of PSII-M and PSII-NRC samples from the ΔΔΔΔHis47 strain. (D) Summary table of the low-molecular mass subunits in ΔΔΔΔNRC detected by intact MS, including example fragment ions.

if small amounts of D1 and D2 are present below their detection limits, they are not stoichiometric components of this complex.

For a more complete identification of the LMM subunits in this complex, we employed MS to measure the mass of the intact protein components. We detected 10 LMM subunits in the control ΔΔΔΔΔHis47 strain, whereas only 7 of those 10 were present in the identified complex (Fig. 2D, SI Appendix, Figs. S3 and S4, and Datasets S4 and S5). Remarkably, the 3 missing subunits are the 3 LMM components of the PSII RC: PsbE, PsbF, and PsbI. Taking our SDS/PAGE, immunoblot, and MS results together, we conclude that the subcomplex specifically lacks all 5 of the PSII RC components—D1, D2, PsbE, PsbF, and PsbI—but contains the rest of the PSII subunits observed in the control PSII-M sample. We therefore refer to it as the “no-reaction center” complex. The presence of the NRC in the His47 strain, seen through native gel, glycerol gradient, MS, and immunoblot characterization, demonstrates that this complex does not form as a result of the absence of PsbO in the ΔΔΔΔΔHis47 strain. Unless otherwise mentioned, the experiments described below were, therefore, performed using the NRC from ΔΔΔΔΔHis47 cells because of the higher yield obtainable in this strain.

**Determination of the Size of the NRC Complex.** The SDS/PAGE, Western blot, and MS results presented above identified the individual proteins in a denatured NRC sample. To determine the absolute MW of the intact, native complex, we used analytical ultracentrifugation (AUC). Distributions of the Chl-containing species of the PSII-M and NRC samples were determined from sedimentation velocity experiments using AUC (Fig. 3A). The NRC sample showed a major species at 6.1 S (Svedberg coefficient) (Fig. 3A, peak b), the molecular mass of which was determined as 167.0 ± 5.3 kDa in a subsequent sedimentation equilibrium experiment (Fig. 3B). A minor species at 2.9 S was also observed (Fig. 3A), with a molecular mass of 75.0 ± 3.5 kDa (Fig. 3B), which likely corresponds to dissociated CP47 (76 kDa) or CP43 (67 kDa) with their associated cofactors. For MW determination, the sedimentation equilibrium curves were analyzed using a 2-species fit based on the observation of 2 species from the sedimentation velocity experiments. The PSII-M sample showed a major species at 11.6 S (Fig. 3A, peak f), and 3 minor species at 2.9 S, 5.4 S, and 9.0 S. The molecular mass of the major species was estimated as 436 kDa, with a best-fit frictional coefficient ratio of 1.27, comparable to the MW of the PSII monomer determined in a previous study by Zoumi et al. (29), using a similar method. The 3 minor species likely represent dissociation products.

**The NRC Complex Lacks a Functional RC.** The absence of the RC proteins in the NRC suggests that the complex cannot function as an RC. To test this hypothesis, we used ultrafast time-resolved fluorescence (TRF) measurements on the PSII-M and NRC samples. Both samples were excited at 625 nm, corresponding to a vibronic overtone of the Chl a Qy band, and the Chl a fluorescence decay was monitored (Fig. 4 A and B, shown as pseudocolor 2D plots). The profiles revealed two components with lifetimes of 4.6 ns and 250 ps, respectively. The longer component, with a lifetime of 4.6 ns, was very similar to the fast NRC component, suggesting that both originate from the same species. The lifetime of 4.6 ns closely resembled that obtained for isolated CP47 and CP43 proteins (31), implying that no further excitation energy transfer occurs in the NRC complex, and this component corresponds to intrinsic decay of excited Chl a. Overall, these results demonstrated that excitation energy in PSII-M that was initially localized on Chl a bound to CP47 and CP43, was efficiently transferred to the RC. These PSII-M results closely mimic those obtained for PSII core complexes from the cyanobacterium Thermosynechococcus vulcanus under similar conditions (30). The slower NRC component, however, with a lifetime of 250 ps, was very similar to the fast NRC component, suggesting that both originate from the same species.

The lifetime of 4.6 ns closely resembled that obtained for isolated CP47 and CP43 proteins (31), implying that no further excitation energy transfer occurs in the NRC complex, and this component corresponds to intrinsic decay of excited Chl a. Overall, these results demonstrated that excitation energy in PSII-M that was initially localized on Chl a bound to CP47 and CP43, was efficiently transferred to the RC. In contrast, no such RC energy trap exists in the NRC complex, and excitation energy remained localized on CP47 and CP43 until it decayed intrinsically.

**NRC Accumulates under High-Light Stress and in the Absence of Protein Synthesis.** As the NRC is a previously unobserved subcomplex of PSII, we wished to determine whether NRC forms during de novo synthesis of PSII or during its repair cycle (SI Appendix, Fig. S1). This can be accomplished by observing whether NRC accumulates or is depleted under PSII-damaging conditions and following the addition of a protein synthesis inhibitor. Accumulation under such conditions indicates NRC formation during the repair cycle, while depletion indicates formation during de novo synthesis. To this end, His47 cultures were treated with either high light (HL, 400 μM photons/m²-s), low light (LL, 40 μM photons/m²-s, normal growth conditions), or these conditions with the addition of 20 μg lincomycin (HL+, LL+) to halt protein synthesis. Cells were harvested when the HL+ culture declined to 50% of the initial photosynthetic efficiency following a move to
HL and addition of lincomycin (F/\textsubscript{iso}) (SI Appendix, Table S1). PSII was isolated from cultures grown under each of these conditions and PSII samples containing 10 μg Chl \textsubscript{a} were run on a clear native PAGE gel (Fig. 5 \textit{A} and SI Appendix, Fig. S5, for actual-color gel scan) to observe differences in NRC abundance. Intensities of each band were analyzed using the LI-COR analysis tool, and the ratios of the NRC/PSII monomer and NRC/PSII dimer were calculated for each condition (Fig. 5 \textit{B}). As seen in Fig. 5\textit{A}, the HL+-treated cells have the highest quantity of NRC, and ratios of the NRC/monomer and dimer that are on average 10 times higher than the control LL condition. LL+-treated cells follow in highest NRC abundance, with NRC/monomer and dimer ratios close to 3 times higher than the control LL condition. The HL-treated cells have a higher abundance of NRC (NRC/monomer and dimer ratios close to twice as high) than the LL control treatment, but the response is modest compared to those cells with impaired protein synthesis.

**Discussion**

In this study, we discovered and characterized the NRC complex, a PSII subcomplex that contains the inner antenna subunits CP43 and CP47, Psb27, and 7 LMM subunits, but is missing the 5 subunits that comprise the PSII RC: D1, D2, PsbE, PsbF, and PsbI. An assembled complex without all 5 RC components has not been described before. Through analytical sedimentation experiments, we determined the molecular mass of the NRC complex to be 167.0 ± 5.3 kDa. This value is in between the sum of the apo- (153 kDa) and holo- (194 kDa) masses of the NRC proteins, indicating that some NRC cofactors with D1 or D2 interfaces may be destabilized in their absence. The determined molecular mass is also close to the sum of the apparent masses of the individual CP43 and CP47 precomplexes (around 180 kDa) measured previously (32). These results are not consistent with the NRC sample comprising a mixture of separate CP43 and CP47 precomplexes, as each of these precursors have MWs roughly half of the determined MW. NRC is also not a mixture of homodimers of the CP43 and CP47 precomplexes. Given the respective sizes of the 2 precomplexes (32), such dimers would differ in mass by around 40 kDa, not consistent with the observed single, narrow, symmetrical major peak (Fig. 3, peak b), indicating a single species. Homodimers were also not detected during previous characterization of the precomplexes (32). Overall, the analytical sedimentation results indicate that the NRC complex is a single species likely composed of a single copy of each of the PSII subunits identified within.

The LMM subunits identified in NRC are consistent with the PSII crystal structures (2, 4, 5) in that all share interfaces with either CP43 or CP47 (except PsbY, which interfaces with another NRC subunit, PsbX). PsbH, PsbL, and PsbT were previously identified in the CP47 precomplex, and PsbK in the CP43 precomplex (32), consistent with our results. The presence of Psb27 is reasonable because it binds to CP43 (21, 28, 33), and the absence of Psb28 (Fig. 2 \textit{B} and \textit{C}) is also reasonable as Psb28 associates closely with PsbE and PsbF (25) and would not be expected to bind in their absence.

In the crystal structures of mature PSII, D1 and D2 bridge the gap in the transmembrane region between CP43 and CP47. In their absence, the NRC subunits do not form a continuous structure, except for a very small overlap between PsbL and PsbT at the cytosolic surface. A significant CP43–CP47 interface would likely be necessary to preserve the structural integrity of this complex and could occur with CP43 and CP47 approaching each other and at least partially closing the gap left by D1 and D2. To test whether NRC occurs as an intermediate in the PSII repair cycle or as an intermediate in de novo PSII synthesis, we exposed His47 cells to HL to induce PSII damage and to lincomycin to stop protein synthesis, both separately and in...
Weisz et al. PNAS October 22, 2019 vol. 116 no. 43 21911

combination with each other. If the NRC were an intermediate in the PSI repair cycle, formed as a result of damage to intact PSI, we expect that it would accumulate in HL, which causes increased PSII damage, and in the absence of protein synthesis, which would otherwise deplete existing NRC as D1 and D2 are resynthesized and inserted into the complex. Conversely, if the NRC were an intermediate in de novo PSI synthesis, we expect that NRC levels would remain stagnant or decrease in the absence of protein synthesis, as combination with newly synthesized D1 and D2 could not take place. Our results showed that the NRC increased in abundance by 2.2- and 2.7-fold compared to the PSIII monomer and dimer, respectively, when His47 cultures were put into HL conditions damaging to PSI. A similar increase of 2.8- and 2.9-fold compared to monomer and dimer, respectively, was observed upon addition of lincomycin to stop protein synthesis under control LL conditions. The largest NRC increase, of 8.1- and 10.9-fold compared to monomer and dimer, respectively, occurred when cells were exposed to both HL and the presence of lincomycin (Fig. 5). These results are consistent with a model of the PSI lifecycle in which the NRC is an intermediate subcomplex in PSI repair and is not consistent with its formation during de novo synthesis. Furthermore, as more NRC accumulates in the absence of protein synthesis than in HL alone, we conclude that the NRC subunits are re-incorporated into repaired PSII when newly synthesized D1 and D2 become available, deplete the level of the NRC in the thylakoid and completing the PSIII repair cycle (Fig. 6). Our observation that the NRC:dimer ratio increased slightly more than the NRC:monomer ratio in all 3 conditions is consistent with this model, as photodamaged PSIII dimers dissociate into monomers early in the PSIII repair cycle.

Assignment of the NRC to the repair cycle also helps explain why this complex has not previously been detected. Most studies of PSI subcomplexes have focused on the assembly of PSIII, not the intermediates that form following photodamage. Many of these studies used mutants that block assembly before formation of active PSI (e.g., ΔCtpA, ΔD2, ΔCP43, or ΔCP47 strains). This valuable strategy has enabled isolation of numerous de novo assembly intermediates, but as active PSIII is never formed in these strains, it has precluded the possibility of observing NRC (27, 28, 34, 35). The currently known steps in the PSIII repair process are: 1) Dissociation of the extrinsic proteins PsbO, PsbU, PsbV, and PsbQ (36); 2) rebinding of Psb27 (22); 3) monomerization of the complex (36); 4) an undefined further dissociation step (20); 5) D1 degradation (37–39); 6) insertion of a new D1 copy (14); and 7) PSIII reassembly (14). Within this known framework, NRC formation would most logically occupy step 4, the undefined dissociation step, with the damaged Psb27-PSII monomer splitting into RC and NRC components (Fig. 6; note that steps 1 to 3 are omitted in Fig. 6 and SI Appendix, Fig. S1 for clarity). An implication is that D1 (and D2) replacement would occur at the level of the RC complex (Fig. 6), not at CP47 as has been previously proposed (SI Appendix, Fig. S1) (14, 20, 40). Meanwhile, the longer-lived (15) CP43 and CP47 would be sequestered efficiently in one location, ready to be recycled back into PSI after synthesis of a new D1 and D2 (15). Dissociation of PSI into RC and NRC complexes following photodamage would allow maximal access for proteases to both D1 and D2, whereas, by interacting closely, CP34 and CP47 would shield each other from such protease attack (41). The recent interesting finding that PSIII can remain stable and fully intact following Mn cluster removal (42) supports the notion that there may be an important efficiency benefit to maintaining a PSI subcomplex, once assembled, in as intact a state as possible, while still allowing for necessary repair to occur.

Damaged PSI is a liability because aberrant PSIII photobiology could result in further oxidative damage to the complex. During PSIII assembly, D1 processing is a checkpoint that prevents premature formation of the highly oxidizing Mn cluster, which could result in damage to nearby subunits (27). The dissociation of the extrinsic proteins and the rebinding of Psb27 following photodamage likely achieves the same goal: Inactivation of the Mn cluster at a time when it could only cause further damage. The formation of the NRC complex can be understood in a similar manner. In addition to being an efficient disassembly/reassembly mechanism, separating into RC and NRC complexes following initial damage to D1 or D2 could serve a 2-fold protective purpose:

![Fig. 4. TRF of ΔO-PSII-NRC and ΔO-PSII-M samples. (A and B) Two-dimensional pseudocolor fluorescence decay profiles at 77 K upon excitation at 625 nm. (C and D) Global analysis results of TRF datasets. Dashed profiles (Fluo) correspond to time-integrated spectra and mimic steady-state fluorescence spectra. All profiles were normalized at their maxima for better comparability. (E) Exemplary kinetic traces at 682 nm (maximum of fluorescence emission from CP47/CP43) accompanied with instrument response functions (IRF). Substantial shortening of fluorescence decay of the ΔO-PSII-M sample is associated with rapid excitation energy transfer from antenna into the PSI core (excitation trapping by reaction center). The different signal rise observed in the 2 traces originates from different temporal resolutions of time windows in which data were collected as demonstrated by IRF. EAFS, evolution associated fluorescence spectra.](image-url)
and subjected to LC-MS/MS. For detailed MS methods and data analysis, see SI Appendix, SI Methods.

In-Solution Digestion and LC-MS/MS Analysis. Samples each containing 2 μg Chl a of ΔpsbO-PSII-M and ΔpsbO-NRC were precipitated using the 2D Cleanup Kit (GE Healthcare). The pellets were resuspended in 20 μL 8 M urea, 50 mM ammonium bicarbonate (ABC). Lys C was added at a 1:50 (wt/wt) protease:sample ratio and incubated at 37 °C for 2 h. Samples were diluted to 1 M urea with 50 mM ABC and trypsin was added at a 1:50 (wt/wt) protease:sample ratio. The samples were incubated overnight at 37 °C, then acidified to 1% formic acid and centrifuged to remove any insoluble material. Digests were analyzed by LC-MS/MS as described in ref. 25. For detailed methods, see SI Appendix, SI Methods.

MS of Intact Proteins. ΔO-M and ΔO-NRC samples, each containing 1.4 μg Chl a, were precipitated using the 2D Cleanup Kit (GE Healthcare). The pellets were resuspended in 100 μL 70% acetone, 19% water, 10% isopropanol, 1% formic acid (vol/vol) (32), diluted 1:3 in the resuspension solution, and infused directly into a Synapt G2 HDMS mass spectrometer (Waters). For detailed methods, see SI Appendix, SI Methods.

Ultrafast TRF Spectroscopy. All spectroscopic measurements were carried out at 77 K, using a VNF-100 liquid nitrogen cryostat (Janis). The samples were diluted in 60:40 (vol/vol) glycerol:RB buffer with 0.04% DM, that after cooling, formed fully transparent glass. Steady-state absorption spectra were recorded on a UV-1800 spectrophotometer (Shimadzu). TRF imaging was performed using a universal streak camera system (Hamamatsu) based on an NS1716-04 streak tube and A6365-01 spectrograph from the Bruker Corporation coupled to an ultrafast laser system, described previously (50). For more detailed methods and data analysis, see SI Appendix, SI Methods.

Analytical Sedimentation. After sample concentration following glycerol gradient ultracentrifugation (see above), ΔO-M and ΔO-NRC samples were buffer-exchanged into RB buffer pH 6.5 containing 5% glycerol. Sedimentation velocity experiments were performed with an Optima XL-A analytical ultracentrifuge and An50 Ti rotor (Beckman Instruments) at 42,000 rpm (25 °C), as described previously (51). The experiment was performed at 4 and 13 μg/mL Chl a, while monitoring absorbance at 437 nm, with the results consistent at both concentrations. Data were analyzed using SEDFIT (52), to obtain c(s) distributions. The c(s) distribution function defines the populations of species with different sedimentation rates (sizes) and represents a variant of the distribution of Lamm equation solutions (52). The density and viscosity of the RB buffer at 25 °C were determined using SEDNTERP; 0.76 m2/g was used as the partial specific volume (29).

Sedimentation equilibrium experiments were performed with the NRC sample at the 3 indicated speeds (25 °C) starting at the lowest and finishing at the highest speed, as described previously (53). Next, 110 μL of the buffer was loaded to an Epon charcoal-filled 6-channel centerpiece. Absorbance data were collected at intervals of 0.003 cm in the step mode with 5 averages per step. Data were edited using SEDFIT to extract concentration profiles from each chamber and analyzed using SEDPHAT with the Species Analysis with Mass Conservation model (54).

PSII Damage Induction. His47 cells were grown to late log phase under conditions described above, and then divided and allowed to grow for 3 h before being subjected to either HL and lincomycin (400 μmol photons/m²s and 20 μg/mL lincomycin), HL without lincomycin, LL with lincomycin, and LL without lincomycin. After 5 h under these conditions, when photosynthetic efficiency decreased to 50% for the HL and lincomycin treatment, cells were harvested and PSII was isolated as described above. Photosynthetic efficiency (F0/Fm′) was monitored using an FLS-200 fluorometer (PMS).

ACKNOWLEDGMENTS. We thank Dr. Alexander Kozlov for helpful discussions. This work was supported by the Chemical Sciences, Geosciences, and Biosciences Division, Office of Basic Energy Sciences, Office of Science, US Department of Energy (DOE) Grant DE-FG02-98ER20230 (to H.B.P.); the Photosynthetic Antenna Research Center, an Energy Frontier Research Center funded by the US DOE, Office of Basic Energy Sciences Grant DE-SC001035 (to H.B.P., R.E.B., and M.L.G.); NIH Grant P41GM103422 (to M.L.G.); and NIH Grant GM030498 (to T.M.L.). V.M.I. was supported by a training Grant T32 EB014855 from the National Institute of Biomedical Imaging and Bioengineering, NIH.
